THURSDAY, MAY 2, 1895.

THE BOOK OF THE DEAD.

The Papyrus of Ani in the British Museum. The Egyptian text with interlinear transliteration and translation, a running translation, introduction, &c. By E. A. Wallis Budge, Litt. D., Keeper of Egyptian and Assyrian Antiquities. Printed by order of the Trustees, 1895. (London: Longmans, Kegan Paul, &c.)

PERHAPS one of the most attractive and popular departments of science is that which treats of the early customs and beliefs of primitive man. Within recent years considerable attention has been directed to this subject. Not only have specialists, such as Mannhardt, Waitz, Bastian, and Tylor, to mention a few prominent names, devoted themselves to the collection and classification of material, but a great body of the reading public have followed their labours with intense interest, and have embarked on a course of original inquiry on their own account. The chief reason for this widespread study of comparative religion is to be sought in the fact that no demands are made on the student for any special training in order that he may appreciate its methods and results. Let him but have the passion of the collector and a love for his subject, and he is fully equipped for his work; all he requires beside are books that will yield reliable information concerning the folk-lore or superstition of any early or primitive race. Readers of NATURE, therefore, will be interested in hearing some account of a remarkable work, recently published by the Trustees of the British Museum, which deals with the religion of the oldest nation in the world whose records have survived to the present day.

The nation to which we refer, it is needless to say, are the Egyptians, whose civilisation on the banks of the Nile stretches back into a remote antiquity. Both the art and literature of this people were in the main the product of their religious belief in a future existence; what we possess of the former we owe to its preservation in the tomb, while a great part of the latter has come down to us in a body of religious compositions to which Egyptologists have given the comprehensive title of "The Book of the Dead." It is with "The Book of the Dead" that the work in question deals. In the year 1888 the Trustees of the British Museum acquired the largest and most perfect specimen of this composition as preserved by that class of papyri which date from the second half of the eighteenth dynasty (about B.C. 1500–1400). About four months ago the Trustees published a second edition of the *facsimile* of the papyrus, and now Dr. Wallis Budge, the Keeper of Egyptian and Assyrian Antiquities, has produced a volume dealing exhaustively with the contents of this unique document.

It would be impossible to treat at any length in a short review the many problems discussed in the work before us. We can, however, briefly indicate its general scope and contents. Dr. Budge has given a transliteration and literal translation of the hieroglyphic text, arranged interlinearly, which will be of great value to the student. This is followed by a running translation, together with a description and explanation of the various vignettes with which the papyrus is profusely illustrated—a portion of the work which will be welcomed by the general reader. Perhaps of even greater importance, however, is the Introduction. Here the author has traced in detail the history and growth of "The Book of the Dead," from its first appearance on the Pyramids of the fifth dynasty to its latest hieratic recension in the early centuries of the Christian era. From the hands of the priests of Hierapolis we follow the work to Thebes, where we first find it divided into definite sections or chapters, each with its distinctive title. Thence, through the closely allied version of the twentieth dynasty to Saïs, where each chapter received its definite place in the series, and the order there introduced continued in use down to the Greek occupation of the country. Having laid before the reader a critical digest of the external history of the work, Dr. Budge then turns to internal questions, and proceeds to summarise the chief aspects of Egyptian belief, supporting each of his theses with citations from the native literature. He treats at length of the legend of Osiris, so closely connected with the doctrine of eternal life, and thence passes to the Egyptian idea of God. This section is followed by a detailed

description of the gods of "The Book of the Dead," and of the principal geographical and mythological places mentioned therein. The practical side of Egyptian worship then engages our attention, and we see the priest performing the complicated system of ritual and ceremony that accompanied the burial of the dead; and, the ground having thus been cleared, one passes on to a consideration of the Papyrus of Ani itself. Ani, in whose honour the work was written, was chancellor of the ecclesiastical revenues and endowments of Abydos and Thebes. From the fact of his exalted official position, therefore, we may, with Dr. Budge, regard his Papyrus as "typical of the funeral book in vogue among the Theban nobles of his time."

In the course of the Introduction Dr. Budge has admirably distinguished the uses of the Egyptian word *neter*, which correspond to a transition from anthropomorphic and polytheistic ideas to a lofty monotheism. The derivation of the word is a moot point among Egyptologists, though all agree in rendering the word by "god." Its original signification, however, may be disregarded, for it does not affect the later history of the word, with which we are at present concerned. Whatever its origin, there is no doubt that the singular *neter* is often used to express an entirely different conception to that conveyed by *neteru*, its plural, the former being employed to designate a supreme god, the latter a number of powers and beings, which were held to be supernatural, but were finite and endowed with human qualities and limitations. The truth of this will be evident to any one who will read through the passages collected by Dr. Budge in support of his contention. Dr. Budge cites the similar difficulty that attaches to the interpretation of the Hebrew word *elohim*, a comparison that might be dwelt on with advantage. One point of difference, however, may here be noted. In the history of the Hebrews we can point to the exact period when the radical change from polytheism to the belief in one god took place. With the rise of the prophets in the ninth century B.C. the nation imbibed the loftier conception, and they assimilated the prophetic teaching with such effect, that, during the post-exilic collection of the national literature, all traces of their former polytheism were as far as possible obliterated. In their literature, therefore, as it has reached us, the earlier national beliefs have survived only in indirect allusions and in the form of single words. With the Egyptians, on the other hand, this change in conception can be ascribed to no particular epoch. We find the idea of a supreme god in existence as early as the fifth dynasty; yet throughout the whole period of Egyptian history there existed side by side with it the lower conception of half-human deities, and the belief in an eternal and infinite god was not considered inconsistent with legends concerning lesser deities, who could eat and drink, and, like men, grew old and died.

To this tolerance, or rather attachment, displayed by the Egyptians for their legends and traditional beliefs, students of comparative religion at the present day owe a lasting debt of gratitude. For many of the legends preserved in late papyri have been handed down unchanged from earlier times, while the earlier monuments themselves have escaped the fury of the iconoclast. We will refer to one such legend cited by Dr. Budge. In a text of the fifth dynasty, the deceased king Unas is described in the form of a god as feeding upon men and gods. He hunts the gods in the fields, and, having snared them, roasts and eats the best of them, using the old gods and goddesses for fuel; and, by thus eating their bodies and drinking the blood, he absorbs their divine nature and life into his own. Many parallels to this quaint legend might be cited from the primitive beliefs of other races.

We cannot conclude without a reference to the unpolemical spirit in which the book is written, which is perhaps the result of a scientific training in Semitic languages and literature having been brought to bear on the difficult problems of Egyptian religion. Throughout the work it is evident that one of the chief aims of Dr. Budge has been to assist the reader to understand the evidence which documents nearly 7000 years old are here made to produce, and to judge of its value for himself. To the anthropologist and the student of comparative religion we, therefore, believe the work will be equally valuable.

THE POLLINATION OF FLOWERS.

Over de Bevruchting der Bloemen in het Kempisch Gedeelte van Vlaanderen. By J. Mac Leod. With 125 Figures. (Gent: Vuylsteke, 1894.)

THIS book is prefaced with a historical introduction which traces the study of the biology of flowers from the appearance of the work of Camerarius in 1691 to the present day. Not only does the author give an account of the work of the various writers, but he also devotes a good deal of space to criticising their conclusions, and comparing them with one another. Of these criticisms, it may be noticed, that he considers that too much importance has been ascribed to the colours of flowers in attracting insect-visitors, and he adduces several facts in support of his view. From these examples it appears that there are certainly some cases in which the bright colours of flowers have not got the object of attracting insects; yet surely in the vast majority of cases, whether the development of bright colours was primarily for this object or not, the showy floral leaves act as advertisements to catch the eye of wandering insects. As the author substitutes no definite theory to account for the colouration of flowers, it seems probable that the old view will hold its ground.

The greater part of the book (about 430 pp.) is taken up with an account of the floral mechanisms of the plants found in East and West Flanders. The mechanisms of a large number of species are carefully described, and the descriptions are illustrated by many good woodcuts, in great part original, in a few cases borrowed from other authors. At the conclusion of the description of each species a list of their insect-visitors is given; these lists appear to be very complete, and will doubtless be useful for reference.

The latter part of the work is largely taken up with an endeavour to find a parallelism between the annual evolution of the various classes of plants and insects, classified according to their mutual biological relations. But the author admits that this attempt has not been successful.

The last section to which we would call attention is that which contains a description of a theory to explain why some plants are adapted for direct fertilisation, and others for crossed fertilisation. According to this theory, entomophilous plants have to make certain sacrifices in order to attract visitors in the shape of the substances needed in the formation of nectar and various perfumes, which are, to a large extent, drawn from the reserve-materials contained in the plant at the time of flowering. If these reserve-materials are present in considerable quantities, the plant will be able to produce much nectar, &c., and will attract many insects, and become adapted to crossed fertilisation. If, on the other hand, it has but little of these stores, it will be able to expend very little in attracting insects, but will have to keep the great part of its scanty stores for the maturation of its fruits and seeds. The consequence will be that the flowers of these latter plants will be but little visited by insects, and will become adapted to self-fertilisation. The author, while he admits that this theory is insufficient to explain certain observations, yet maintains that it is more general in its application than Warming's idea expressed with regard to the flora of Greenland. According to this latter author, crossed fertilisation may be considered the rule in the case of those plants which multiply rapidly by vegetative reproduction, while plants without this second method of reproducing their kind, and which must necessarily bring their seeds to maturity, are most usually adapted to self-fertilisation. It is, however, most probable that neither of these theories should be regarded as in itself giving all the determining causes for a plant becoming adapted to crossed or self-fertilisation, but as only expressing two of, it may be, many factors which are at work in moulding any given plant for one form of fertilisation or another. H. H. D.

OUR BOOK SHELF.

Emile Levier. A travers le Caucase. Notes et Impressions d'un Botaniste. 8vo. pp. 348. (Paris: Libraire Fischbacher.)

DR. LEVIER accompanied his botanical friend, Signor Stephen Sommier, on a tour through the Central Caucasus in 1890, the object being mainly to collect and study the flora of the mountains. The letters which he sent to his friends recording his impressions were published in a magazine without his knowledge, although not written for the public, and the present volume is practically a republication of the letters, edited by the author, and illustrated by numerous sketches and reproductions of photographs. Amongst the latter are several of Signor Vittorio Sella's fine pictures of Caucasian scenery, which, however, are not done justice to in the process blocks. The botanical results of the journey have been published for the most part in the *Bulletin* of the Italian Botanical Society, and only a list of the sixty-nine new species found is given in the book, such references to botany as occur in the text, though full of interest and presenting some acute generalisations, by no means preponderating over the miscellaneous observations of an intelligent tourist, and the pleasantly narrated incidents of travel. A list of thirty-seven species of lepidoptera collected by Dr. Levier is also given.

The two botanists were accompanied by an Italian peasant as hunter, cook and general assistant; and together they experienced few difficulties and no danger on their journeys through unfrequented regions for four months. After some excursions in the neighbourhood of Batum and of Tiflis, they started from Kutais for the journey across the range, going up the valley of the Rion and across the Latpari Pass into Swanetia. After traversing the valleys of Swanetia and Abkhasia, and making an excursion up the valley of the Kukurtli on the western slope of Elburz, they reached the northern plain by the valley of the Kuban. They returned to Tiflis by the coach road from Vladikavkas through the Dariel Pass heavily laden with more than ten thousand botanical specimens, the drying of which was a never-failing source of surprise and amusement to natives and Russian officials alike.

The spirit of holiday and nature-worship breathes through the whole book. Rarely, we believe, is a traveller in untrodden ways so able to appreciate to the full the delights of his surroundings as this light-hearted Swiss physician, whose high spirits and good-humour retain contagious qualities even through the pages of his book.

H. R. M.

Science Readers. By Vincent T. Murché. Books i. to iii. (London: Macmillan and Co., 1895.)

IN elementary schools where the rudiments of knowledge about properties and things are taught, these books may be introduced with advantage as reading books. The style is conversational, and every effort appears to have been made to convey the information in simple language, as well as to make it interesting.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Origin of the Cultivated Cineraria.

IN the recent discussion at the Royal Society, I used as an illustration of the amount of variation which could be brought about under artificial conditions in a limited time, the case of *Cineraria cruenta*, which I regarded as having given rise to the cultivated Cineraria.

This Mr. Bateson describes as "misleading."

I have read all he has to say, and, with the assistance of competent members of my staff, have carefully examined authentic specimens of all the species he names as having had a share in the parentage of the Cineraria.

Those species, if I understand him rightly, are four in number: *cruenta*, *aurita*, *populifolia* and *lanata*. They were all introduced into English horticulture, through Kew, between 1777 and 1780, and were figured and described by L'Héritier in his "Sertum Anglicum."

A technical discussion of the subject would necessarily take up a good deal of space, and would not be very interesting to readers of NATURE. Mr. Bateson refers to De Candolle's "Prodromus." It will be sufficient, perhaps, to say that had he studied that authority with care, he would have found that while *cruenta* is, like the modern Cineraria, herbaceous, *aurita*, *populifolia* and *lanata* are shrubby species. Further, while the modern Cineraria retains the exact foliage of *cruenta*, that of *aurita* and *populifolia* resembles the foliage of the white poplar; "folia populi albæ." Apart from the additional fact that *populifolia* has yellow flowers, I think I may confidently appeal to even the non-botanical eye as to whether the modern Cineraria exhibits anything of the white poplar character about it. As to *lanata*, its general aspect is sufficiently indicated by its specific name. It is represented by numerous specimens in No. 4 House at Kew, where Mr. Bateson may inspect it. He will probably then regret, for the sake of his reputation as a naturalist, that he committed himself to print on a subject on which he evidently possesses little objective knowledge.

I may add that in the discussion at the Royal Society, Mr. Bateson asserted to my surprise that the cultivated varieties of the *Camellia* could be distinguished by their leaves alone. I

interjected a doubt, but next day I carefully examined a large number of specimens here with a member of my staff, and we totally failed to confirm Mr. Bateson's statement.[1]

Royal Gardens, Kew, April 29.

The Unit of Heat.

MR. GRIFFITHS, in a recent communication to the Royal Society, has called attention to the indefiniteness attending our present knowledge of the heat unit. In this connection I would wish to suggest—what indeed has long been present in my mind—that a unit of heat other than the present calorie is desirable. The present thermal unit is highly arbitrary, as well as most difficult of verification. This is true, whether we take the temperature at which the calorie is to be measured as 4° C. or 15° C. or as the temperature of minimum specific heat of water. The calorie owes its perpetuation to the method of mixtures—a laborious and inaccurate method of calorimetry—and dates from a period when the variations in the specific heat of water were not held of account.

If we do adhere to a specific heat of water calorie, it will be necessary to proceed as in the determination of the standard metre; obtain the more or less inaccurate measure of the primary unit in terms of some more accessible quantity.

My suggestion is that we start with an accessible unit. I think the latent heat of steam at the standard pressure has first claim. One gramme of saturated steam at 760 m.m. might be assumed to give up the unit quantity of heat in becoming water, without change of temperature. This unit might be called a therm, in order to avoid confusion with the existing unit. The specific heat of water would then stand as about 1·8 milli-therms. The larger value of the new unit commends itself as being more applicable to the problems of applied science; which, indeed, may be inferred from the fact that engineers often understand by the term calorie the kilogramme-degree.

I am aware that the change proposed is a radical one; but an appreciable change is better than a vexatious correction, and we know now that revision and change are inevitable.

In the definition of the proposed unit we replace the unreliable thermometer by one of the most trustworthy of instruments—the barometer; and our quantities of heat may be determined by the chemical balance, and, at 760 m.m., read directly upon the weights. We are sure of the purity of the material.

Trinity College, Dublin. J. JOLY.

The Study of Earthquakes in the South-East of Europe.

IN two recent notes in NATURE (vol. li. pp. 180, 468) attention has been drawn to the foundation by the Ottoman Government of a geodynamic section of the Imperial Meteorological Observatory at Constantinople. The new department has been placed under the direction of Dr. G. Agamennone, who for several years held a similar office at Rome, and who is well known to seismologists for the valuable work performed by him in Italy.

Not content with the foundation of a seismological observatory, Dr. Agamennone has also undertaken the organisation of earthquake studies throughout the Ottoman Empire, and he is anxious to extend this very important branch of his work so as to include the entire district within and bordering the eastern end of the Mediterranean. As there must be many readers of NATURE who are able, either directly or indirectly, to aid him in this attempt, I should be grateful if you would allow me to recommend it to their attention and support. Dr. Agamennone's address is "Observatoire Impériale Météorologique, Constantinople (Pera)."

That one of the most seismic regions of the globe should at last attract the organised study it deserves, and that the initiation of the requisite observations should have fallen into hands so experienced and capable, will be matters of gratification to those who are interested in the progress of seismology. No less desirable would it be that all the results of such observations should be contained in the pages of a single journal, and Dr. Agamennone's publication of a monthly seismic bulletin, of which the first two numbers have already been issued, is an additional reason for the concentration of records from the different countries concerned in the Turkish Office.

Birmingham, April 19. CHARLES DAVISON.

[1] This and the absence of variation from the feral form in the foliage of the cultivated Cineraria, are covered by the principles laid down by Darwin in "Animals and Plants under Domestication," vol. ii. pp. 17-220.

Uniformitarianism in Geology.

IN reference to Prof. Judd's excellent statement of the position of the uniformitarian, allow me to call attention to an argument which tends to show that, so far as earthquakes and volcanic eruptions are concerned, catastrophes may be of greater magnitude now than in earlier geologic times.

The violence of an explosion will depend largely on the amount of confinement and pressure to which the exploding compounds are subject, as well shown in the case of Kilauea where there is a constantly open vent and no violent eruptions as contrasted with the numerous catastrophic explosions of long dormant volcanoes whose vents had become sealed up with cores of solid lava. But it is admitted that the crust of the earth has been growing thicker during all geological time. It is therefore almost certain that, in the remoter epochs volcanic phenomena were more frequent but less violent than they have become now that the crust is thicker, and, in its lower portions, at all events, denser and more consolidated. The usual argument, that, because the interior of the earth was somewhat hotter in early times therefore volcanic phenomena were more violent, appears to me to be entirely fallacious. The liquid matter immediately below the crust would have been at the same temperature then as it is now; and if there were a more abundant supply of aqueous vapour and other gases, the thinner and more permeable crust would have allowed of their constant and comparatively easy escape.

I do not remember to have seen this consideration referred to in any discussion of the question, and I therefore submit the argument to the judgment of physical geologists.

ALFRED R. WALLACE.

Research in Education.

PROF. ARMSTRONG's trenchant indictment of the present methods of teaching science, is a little too much akin to Carlyle's fulminations against things in general—destructive but not constructive. Probably all good teachers are agreed upon the pernicious futility of the text-book and lecture-room cram system, and are in thorough accord as to the educational value of practical work; and are waiting only to learn or discover the best system of employing it. To this end destructive criticism helps but little. What is wanted is some definite scheme of work constructed by masters of practical instruction. Prof. Armstrong does certainly advocate what may be termed the "research method"; but it does not elucidate the question much, for it is difficult to understand how far he would extend this method. Would he, for instance, never mention Dalton's laws to students until, by a series of analyses, they were in a position to discover them for themselves? Or in the case of specific heat, how much information should be given before the beginners are set to investigate the phenomena alone? There are two ways of learning practically physical and chemical truths, either by repeating methods which have been explained and demonstrated, and then verifying each step by actual contact with real objects, and so acquiring real knowledge of fact and the application of theory, or by struggling to the truth by a process of trial and error. That the latter process, when successful, is the more stimulating to the intellect may be admitted, but that it is practically possible must be doubted. In introducing any new subject to the mind, surely broad outlines should be given first, and details filled in afterwards; observation requires teaching as much as any other faculty. Tyndall tells this story of Faraday. As Tyndall was about to show the latter an experiment, Faraday laid his hand on his shoulder and said, "Wait a minute; what am I to look for?" The application is plain—even Faraday felt the advantage of having the observer fore-armed.

Beginners know not what to observe, and cannot fashion experiments for themselves, and therefore it seems more rational, that students should have the recognised methods of science explained and demonstrated to them, and then be caused to repeat the necessary operations practically, numerical details being varied as in mathematical exercises. When thus equipped with sound theoretical knowledge and fair manipulative dexterity, they will be in a position to embark upon "research"; for they will then have acquired some power of observation, accuracy, and the faculty of making inferences. The "research method" *ab initio* appears like an attempt to teach a child to read before he knows his letters. I am fully conscious of my audacity in venturing into the lists, and am not ignorant of the sort of folk who "madly rush where angels fear to

tread"; but if I can elicit some definite scheme from Prof. Armstrong, I shall regard my own dialectic annihilation as a small price to pay for the ultimate gain. D. S. T. GRANT.

Chemical Laboratory, Lahore, Punjab.

A Lecture Experiment.

To show that chlorine will attack mercury, some mercury was shaken up in a covered gas jar filled with chlorine. On shaking, the sides of the jar and also the cover-glass became coated with a continuous film of mercury, as though the inside were silvered. After a short time, the film was eaten through, and patches of the white chloride produced. I have not seen this effect noticed in books, so it may be worth while to call attention to it.

C. J. WOODWARD.

Municipal Technical School, Birmingham, April 25.

VITALITY OF SEEDS.

THE duration of the vitality of seeds is perhaps the most important of the various phenomena of plant-life, especially when considered in connection with the introduction into a country of the economic plants of other countries. It is a subject that has engaged attention from very early times, and the literature relating thereto is considerable. Much of this, however, is of a traditional and unpractical character; but even if we confine ourselves to the demonstrable, or demonstrated, the subject is almost inexhaustible. There is such an infinity of variety in the behaviour of seeds under different conditions, that it is impossible in a short account, such as this must be, to do more than convey a general idea of the subject. Perhaps the best way to treat the question, apart from technicalities, is to consider the vitality of seeds under ordinary, and under extraordinary, conditions. In the development and germination of seeds, there is, in a sense, usually a period of gestation and a period of incubation, as in oviparous organisms of the animal kingdom; and the duration of these periods is within definable limits, under ordinary conditions, though seeds do not exhibit the same fixity of time in regard to development and vitality as eggs. The embryo of a seed is the result of the impregnation of the female ovum in the ovary or young seed-vessel, by the male element, generated in the anthers; and in the mature state this embryo may fill the whole space within the skin, or testa, of the seed, as in the bean and acorn; or it may be a comparatively minute body, as in wheat, maize, and other cereals: the rest of the seed being filled with matter not incorporated in the embryo. The difference is one of degree in development. In the one case, the growing embryo has absorbed into its own system, as it were, before germination or the beginning of the growth of the embryo into a new plant, the whole of the nutrient material provided in the seed for reproduction; whereas, in the latter case, the process of absorption and utilisation of the "albumen," or nutrient matter, takes place after the seed is detached from the parent plant, and during the earliest stage of growth of the new plant; so that the plant is nourished until it has formed organs capable of assimilating the food obtainable from the atmosphere and earth. Between these two extremes of development of the embryo, or future plant, before organic connection with the parent ceases, there is every conceivable degree and variety; and, as will presently be explained with examples, some plants are viviparous, in the sense that the embryo commences active life before being severed from the parent, so that when this occurs the plant is in a position to draw its sustenance from unassimilated or inorganic materials. Now it is a curious and unexplainable fact that certain seeds exhibiting the extremes of embryonal development, instanced in the bean and wheat, are equally retentive of their germinative power. The longevity, if it may be so called, of seeds is exemplified in "exalbuminous" seeds as well as in "albuminous" seeds of every degree. It should be mentioned, however, that the difference is not so much one of assimilation or development as of the earlier or later transfer of the nutrient matter of the seed to the embryo or plantlet. Assuming the perfect maturation of a seed, certain conditions are necessary to quicken its dormant vitality: and the two principal factors are heat and moisture, varying enormously in amount for different plants, and acting much more rapidly on some seeds than on others, even when the amount required is much the same. Neither under natural nor under artificial conditions will some seeds retain their vitality more than one season; and all the resources of the accumulated experience of seed-importers from distant countries are insufficient in some cases to maintain their vitality. It is not altogether because the interval between the dispersal and the germination of the seed, under ordinary conditions, is necessarily longer; but rather because in the one case the conditions under which a seed will germinate are much more restricted than in the other. Let us now examine the natural conditions under which seeds are commonly produced and dispersed, in relation to the retention of their vitality; and we shall learn how much more it depends on their nature, or natural means of protection, than on the seasons. An oak tree sheds its acorns in autumn, and the leaves which fall afterwards afford them some protection from frost and excessive dryness. But the leaves might be blown away from one spot, and the acorns exposed to intense frost or drought, either of which will speedily kill them. In another spot the leaves may drift into thick layers, with an excessive accumulation of moisture, causing decay of the underlying acorns; and there are many other unfavourable conditions which may destroy the vitality of the acorn. It is apparently impossible, however, to preserve an acorn's vitality by any artificial means for more than one season.

The scarlet-runner bean loses its germinative power on exposure to comparatively slight frost, the degree depending upon the amount of moisture in it; yet it will retain its vitality for an almost indefinite period under favourable artificial conditions. In both of the examples given, germination would naturally follow as soon after maturation as the conditions allowed. The seeds of the hawthorn behave differently. Each haw contains normally three to five seeds, every one of which is encased in a hard, bony envelope, in addition to its proper coat or testa. Committed to the earth, and under the most favourable conditions, these seeds do not germinate till the second year, and often not so soon. In this instance prolongation of vitality is probably due in some measure to the protective nature of the shell enclosing the seed.

Returning to seeds in which the embryo or plantlet forms only a very small part of the whole body, wheat may be taken as a familiar and easily observed illustration of a seed, the vital energy of which requires very little to stimulate it into active growth; and yet this same seed, having no special protection in the way of coating, will retain its vitality as long, perhaps, as any kind of seed, if not under the influence of moisture. The primary condition to the preservation of vitality in a seed is perfect ripeness. Unripe seeds of many kinds will germinate and grow into independent plants if sown immediately after removal from the parent. The facility with which immature wheat will germinate is most disastrously exemplified in a wet harvest, when the seeds will sprout while the corn is standing or in sheaf; thus destroying more or less completely the value of the grain for flour, as the starch or flour is consumed in the development of the embryo, or what is left is so deteriorated by chemical change that it is not good for food. There is perhaps no other seed more susceptible to moisture, and none less affected by dryness, or by heat or cold in the absence of moisture.

The kind of vivipary exhibited by the wheat is occasionally observed in various other plants; and sometimes the seeds of pulpy fruits germinate in the fruit. There is also a class of plants in which vivipary is normal. Prominent in this class are the mangroves (*Rhizophoreæ*, &c.) of muddy sea-shores in the tropics. In these plants there is a remarkable adaptation to conditions, which ensures their reproduction. From the very inception of the embryo there is no apparent interruption of active vitality in its development and germination. In the earliest stage the cotyledons or seed-leaves are formed, and the radicle or future primary root is represented by a very small point. When the former have attained their full development, which is not great, the latter begins to grow and rapidly increases in size. Each fruit or seed-vessel, it should be mentioned, contains only one seed, the rootlet of which points to the apex of the fruit. Soon this rootlet pushes its way through the apex of the fruit, and grows into a spindle-shaped body of great density and length; the cotyledons or seed-leaves remaining partly inside the fruit, and acting as an organ of absorption from the parent plant to nourish the seedling. In *Rhizophora mucronata* this radicle attains a length of two to three feet, and the seedling eventually falls, and by its own weight penetrates and sticks in the mud, leaving the fruit, containing the exhausted cotyledons, attached to the tree, where it dries up. Another singular adaptation to conditions is the vital development of the seeds of aquatic plants which ripen their seeds on or under water. *Vallisneria* is a remarkable instance of this. The unisexual flowers are formed under water: the female on long coiled stalks, which at the right period uncoil, and the flower rises just above the surface of the water. Simultaneously the short-stalked male flowers are detached from the base of the leaf-stalks, and also rise to the surface. After impregnation has taken place, the stalk of the female flower coils up again, and draws the seed-vessel down under water, where the seeds ripen.

It has been explained that heat, moisture, and air are necessary to the germination of seeds, varying immensely for different seeds. We come now to the behaviour of certain seeds under the influence of an unusual or unnatural amount of moisture, heat or cold, especially in relation to the length of the duration of the exposure to any one of these factors. It has been proved beyond dispute, by actual experiment, that the vitality of certain seeds, notably various kinds of bean and convolvulus, is not impaired by immersion in sea-water (or rather floating and partially submerged) for a period of at least one year; and that after having been kept quite dry for two or three years. Plants are actually growing at Kew from seeds treated as described; and some years ago several seeds of *Entada*, cast ashore in the Azores, whither they had been transported by the Gulf Stream, were raised at Kew. So far as at present known, all the seeds that will bear very long immersion without injury have an intensely hard, bony, or crustaceous coat, that would withstand boiling for a minute or two without killing the embryo. Yet it is difficult to understand this power of resistance, especially after being kept dry for a long time. This imperviousness to water explains the wide distribution of many sea-side plants, the seeds of which are conveyed by oceanic currents. How long such seeds would retain their vitality in water is uncertain, because experiments have not reached the limit. Many readers will remember Darwin's experiments in this connection; but it should be borne in mind that they were chiefly with seeds of plants not at all likely to be dispersed by the sea.

It has already been stated that some seeds will bear immersion in boiling water for a short time, and gardeners occasionally practise this treatment to accelerate the germination of hard-coated seeds. But seeds of all kinds will bear for a considerably longer period a much higher dry temperature than soaking in water of the same temperature. It is recorded, by trustworthy authorities, that the seeds of many plants (poppy, parsley, sunflower, and various kinds of grain, for instance) if perfectly dry, do not lose their vitality when subjected to a temperature of 212° F. for forty-eight hours; and for shorter periods to a much greater heat. The result in most cases, though not all, is a considerable retardation of germination. Dry grain is equally impervious to cold. In 1877, seedling wheat was exhibited at the Linnean Society that had been raised at Kew from grain that had been exposed to the intense cold of the Arctic expedition of 1874 to 1876. The next question that arises is: how long do seeds retain their vitality when stored in the ordinary ways adopted by dealers? As a rule, seedsmen and gardeners prefer new seed, because a larger percentage germinates; and mixing old seeds with new, tells its own tale in irregular germination. Nevertheless, there are many seeds that retain their vitality from five to ten years sufficiently well to be depended upon to yield a good crop. Old balsam seed, other things being equal, has the reputation of yielding a larger proportion of double flowers than new; and some gardeners consider that cucumber seed of four or five years of age gives better results than the seed of the previous year. As already mentioned, perfectly ripened seed will retain its vitality longer than imperfectly ripened seed. In illustration of this, we note that carrot seed grown in France retains its germinative power, on the average, longer than English-grown seed, owing to climatal differences.

There is one other natural condition in relation to the vitality of seeds that should be mentioned; that is, the duration of the vitality of seeds on the mother plant. Some of the Australian *Proteaceæ*, and some of the fir trees, especially North American, bear the seed-vessels containing quick seeds of many successive seasons; and only under the influence of excessive drought or forest fires do they open and release the seed. Rapid forest fires are often not sufficient to consume the cones, but sufficient to cause them to open and free the seed for a succession of trees. The unopened cones of thirty years have been counted on some fir trees; and it is averred that the first seed-vessels of some proteaceous trees do not open to shed their seed, under ordinary conditions, until the death of the parent plant, so that a tree may bear the accumulated seed of half a century or more.

Finally, a few words respecting the extreme longevity attributed to certain seeds. The reputed germination of "mummy wheat," from two to three thousand years old, has been the theme of much writing; but the results of careful subsequent experiments with grain taken from various tombs do not support the doubtless equally conscientious, though less skilfully conducted, experiments, supposed by some persons to have established the fact of wheat of so great an age having germinated. Indeed it is now known that the experiments mainly relied upon to prove this long retention of vitality were falsified by the gardener who had charge of them. Nevertheless, there is no doubt that some seeds do retain their vitality for a very long period, as is proved by numerous well-authenticated instances. Almost every writer on physiological botany cites a number of instances. Kidney beans taken from the herbarium of Tournefort are said to have germinated after having been thus preserved for at least 100 years. Wheat and rye are also credited with having retained their vitality for as long a period. Seeds of the sensitive plant (*Mimosa pudica*) kept in an ordinary bag at the Jardin des Plantes, Paris, germinated freely when sixty years old. A long list might be made of seeds that have germinated after being stored for twenty-five to thirty years. If seeds retain their vitality for so long a period as this under such conditions, it is quite conceivable that seeds buried deep in the earth, beyond atmospheric influences, and

where there was not excessive moisture, might retain their germinative power for an almost indefinite period; and the fact that plants previously unknown in a locality often spring up where excavations have been made, bear out this assumption. The same thing happens in arable land, should the farmer plough deeper than usual; and deeper tillage, which would otherwise be beneficial, is often avoided on this account. A careful writer like Lindley states, though without qualification, that he had raspberry plants raised from seed taken from the stomach of a man, whose skeleton was found thirty feet below the surface of the ground. Judging from coins found at the same place, the seeds were probably 1600 or 1700 years old. One more example of seeds germinating that are supposed to have been buried some 1500 to 2000 years. About twenty years ago, on the removal of a quantity of slack of the ancient silver mines of Greece, several plants sprang up in abundance previously unknown in the locality. Among these was a species of *Glaucium*, which was even described as new; and it is suggested that the seed may have lain dormant for the long period indicated. But there is not the amount of certainty about any of these assumed very old seeds to convince the sceptical or to establish a fact. It remains yet for somebody to institute and carry out careful investigations where excavations are being made.

W. BOTTING HEMSLEY.

TERRESTRIAL HELIUM (?).

AT the meeting of the Royal Society on Thursday last (April 25), two papers dealing with the nature of the gas from uraninite were presented. We print both papers in full.

ON A GAS SHOWING THE SPECTRUM OF HELIUM, THE REPUTED CAUSE OF D_3, ONE OF THE LINES IN THE SPECTRUM OF THE SUN'S CHROMOSPHERE.[1]

In the course of investigations on argon, some clue was sought for, which would lead to the selection of one out of the almost innumerable compounds with which chemists are acquainted, with which to attempt to induce argon to combine. A paper by W. F. Hillebrand, "On the Occurrence of Nitrogen in Uraninite, &c." (*Bulletin of the U.S. Geological Survey*, No. 78, p. 43), to which Mr. Miers kindly directed my attention, gave the desired clue. In spite of Hillebrand's positive proof that the gas he obtained by boiling various samples of uraninite with weak sulphuric acid was nitrogen (p. 55)—such as formation of ammonia on sparking with hydrogen, analysis of the platinichloride, vacuum-tube spectrum, &c. I was sceptical enough to doubt that any compound of nitrogen, when boiled with acid, would yield free nitrogen. The result has justified the scepticism.

The mineral employed was cleveite, essentially a uranate of lead, containing rare earths. On boiling with weak sulphuric acid, a considerable quantity of gas was evolved. It was sparked with oxygen over soda, so as to free it from nitrogen and all known gaseous bodies except argon: there was but little contraction; the nitrogen removed may well have been introduced from air during this preliminary experiment. The gas was transferred over mercury, and the oxygen absorbed by potassium pyrogallate; the gas was removed, washed with a trace of boiled water, and dried by admitting a little sulphuric acid into the tube containing it, which stood over mercury. The total amount was some 20 c.c.

Several vacuum-tubes were filled with this gas, and the spectrum was examined, the spectrum of argon being thrown simultaneously into the spectroscope. It was at once evident that a new gas was present along with argon.

Fortunately, the argon-tube was one which had been made to try whether magnesium-poles would free the argon from all traces of nitrogen. This it did; but hydrogen was evolved from the magnesium, so that its spectrum was distinctly visible. Moreover, magnesium usually contains sodium, and the D line was also visible, though faintly, in the argon-tube. The gas from cleveite also showed hydrogen lines dimly, probably through not having been filled with completely dried gas.

On comparing the two spectra, I noticed at once that while the hydrogen and argon lines in both tubes accurately coincided, a brilliant line in the yellow, in the cleveite gas, was nearly *but* not *quite* coincident with the sodium line D of the argon-tube.

Mr. Crookes was so kind as to measure the wave-length of this remarkably brilliant yellow line. It is 587·49 millionths of a millimetre, and is exactly coincident with the line D_3 in the solar chromosphere, attributed to the solar element which has been named *helium*.

Mr. Crookes has kindly consented to make accurate measurements of the position of the lines in this spectrum, which he will publish, and I have placed at his disposal tubes containing the gas. I shall therefore here give only a general account of the appearance of the spectrum.

While the light emitted from a Plücker's tube charged with argon is bright crimson, when a strong current is passed through it, the light from the helium-tube is brilliant golden yellow. With a feeble current the argon-tube shows a blue-violet light, the helium-tube a steely blue, and the yellow line is barely visible in the spectroscope. It appears to require a high temperature therefore to cause it to appear with full brilliancy, and it may be supposed to be part of the high-temperature spectrum of helium.

The following table gives a qualitative comparison of the spectra in the argon[1] and in the helium-tubes.

	Argon-tube.	*Helium-tube.*	
Red ..	1st triplet.	1st triplet.	Equal in intensity.
	2nd pair.	2nd pair.	,, ,,
	Faint line.	Faint line.	,, ,,
	Stronger line.	Stronger line.	,, ,,
	Brilliant line.	Dull line.	Weak in helium.
	Strong line.	Very dim line.	
Red-orange	Moderate Line.	Moderate line.	Equal in intensity.
	,, ,,	,, ,,	,, ,,

	Triplet.	Triplet.	,, ,,
	Triplet.	Triplet.	,, ,,
	Pair.	Pair.	,, ,,

It is to be noticed that argon is present in the helium-tube, and by the use of two coils the spectra could be made of equal intensity. But there are sixteen easily visible lines present in the helium-tube only, of which one is the magnificent yellow, *and there are two red lines strong in argon and three violet lines strong in argon, but barely visible and doubtful in the helium-tube.* This would imply that atmospheric argon contains a gas absent from the argon in the helium-tube. It may be that this gas is the cause of the high density of argon, which would place its atomic weight higher than that of potassium.

It is idle to speculate on the properties of helium at such an early stage in the investigation; but I am now preparing fairly large quantities of the mixture, and hope to be able before long to give data respecting the density of the mixture, and to attempt the separation of argon from helium.

[1] Preliminary Note, by Prof. William Ramsay, F.R.S.

[1] The tube then used was the one with which Mr. Crookes' measurements of the argon spectrum were made. It contains absolutely pure atmospheric argon.

ON THE NEW GAS OBTAINED FROM URANINITE.[1]

ON March 28, Prof. Ramsay was so good as to send me a tube containing a new gas obtained by him from uraninite (cleveite) showing a line in the yellow which was stated to be of the same wave-length as D_3 which I had discovered in 1868. This line Dr. Frankland and myself shortly afterwards suggested might be a line of hydrogen not visible under laboratory conditions, but solar work subsequently showed that this view was untenable, although the gas which produced it was certainly associated with hydrogen.

Subsequently other chromospheric lines were found to vary with the yellow line, and the hypothetical gas which gave rise to them was provisionally named helium, to differentiate it from hydrogen.

It was therefore of great interest to me to learn whether the new gas was veritably that which was responsible for the solar phenomena in question; and I am anxious to tender my best thanks to Prof. Ramsay for sending the tube to enable me to form an opinion on this matter. Unfortunately it had been used before I received it, and the glass was so blackened that the light was invisible in a spectroscope of sufficient dispersion to decide the question.

On March 29, therefore, as Prof. Ramsay was absent from England, in order not to lose time, I determined to see whether the gas which had been obtained by chemical processes would come over by heating in vacuo, after the manner described by me to the Society in 1879, and Mr. L. Fletcher was kind enough to give me some particles of uraninite (Broggerite) to enable me to make the experiment.

This I did on March 30, and it succeeded; the gas giving the yellow line came over associated with hydrogen in good quantity.

I have since obtained photographs of the gas, both in vacuum tubes while the Sprengel pump has been going; and at atmospheric pressure over mercury. To-day I limit myself to exhibiting two of these photographs.

One of the photographs exhibits a series of spectra taken during the action of the pump. The two lower spectra indicate the introduction of air by a leak, after the capillary had cracked near one of the platinums, giving us on the same plate the banded and line spectrum of air. These prove that there was no air present in the tube when the fourth spectrum was taken. This photograph has not yet been finally reduced, but a preliminary examination has indicated that most of the lines are due to the structure spectrum of hydrogen, but not all of them.

Among the lines which cannot be referred to this origin are two respectively near λ 4471, and λ 4302, which have been observed in the chromosphere, 4471 being as important as D_3 itself from the theoretical point of view to students of solar physics.

Whilst spectrum No. 4 was being photographed with the capillary tube end-on wise, eye observations were made in another spectroscope directed sideways at it. I give from the Laboratory Note Book the observations I made while photograph No. 4 was being taken, to show that the yellow line was visible during the whole exposure.

Thursday, April 4, 1895. *Plate F. Exposure 4.*

10 minutes' exposure.

4.42 Exposure started.
4.43 Yellow line brightening up considerably.
4.44 Suddenly as bright as hydrogen.
4.45 Yellow line double.
4.46 Comparison with D gives yellow line in position of D_3.
4.47 Pump much less full, 7 c.c. of gas collected. Yellow line much brighter.
4.48 Air break introduced. Line still visible, but very faint. Hydrogen lines getting brighter, and some fresh lines appearing in green.
4.48.5 Air break and jar removed. Yellow line the only one seen, being as bright as C. Line in green the only other line visible.
4.50 Replaced jar. Yellow brightening and the other lines more refrangible, brightening with it.
4.51 Very bright. Steeple nearly full of gas.
4.52

The lines which appear both in the photographs of the capillary tube and of the gas collected over mercury are as follows. The lines indicated by an asterisk are near lines recorded in the chromosphere by Young or myself, or photographed during the eclipse of 1893:—

Micrometer reading.	Wave-length (Rowland).
3·2495	4581*
·2917	4523*
·2981	4513*
·3234	4479
·3316	4469·5*
·4146	4368
·5740	4196*
·5884	4181
·5933	4177*
·6139	4156*
·6176	4152·5*
·6262	4144*
·6290	4141

With regard to the observations in the visual spectrum, I have not found the uraninite gas to contain the argon lines as given by Mr. Crookes, nor, with the exception of the yellow line, do I get the special lines noted by him in the gas. (Four of these, out of six, seem possibly to be due to nitrogen.)

But I do get lines nearly coinciding with chromospheric lines discovered by me in 1868.

On November 6 of that year I suspected a line less refrangible than C, and so near it that when both were showing brilliantly the pair appeared double, like D in a spectroscope of moderate dispersive power.

Later I discovered another line at 6678·3 (R), which was observed to vary with D_3. There is a line in this position, with the dispersion employed, in the spectrum of the new gas. This line has also been seen by Thalén, as stated by Prof. Cleve in a communication to the Paris Academy (*Comptes rendus*, April 16, p. 835); but the other lines given by him (with the possible exception of the one at 5016), have not been recorded by me.

Although I have at present been unable to make final comparisons with the chromospheric lines, the evidence so far obtained certainly lends great weight to the conclusion that the new gas is one effective in producing some of them, and it is suggested by the photographs that the structure lines of hydrogen may be responsible for others.

I may state, under reserve, that I have already obtained evidence that the method I have indicated may ultimately provide us with other new gases the lines of which are also associated with those of the chromosphere.

Messrs. Fowler, Baxandall, Shackleton and Butler assisted at various times in the investigation.

[1] Preliminary [illegible] Royal Society [illegible]

NOTES.

WE regret to report that Prof. Huxley is still in a critical state of health. The slight improvement noticed in his condition last week appears not to have been maintained. It is more than eight weeks since his illness began with an attack of influenza, from the effects of which he is now suffering.

M. NORDENSKIÖLD has recently discovered a uranium containing mineral which may prove of great interest at the present time. It forms carbonaceous beds of which the ashes contain two to three per cent. of uranium, and, in addition, traces of nickel and rare earths. This uraniferous material is said to yield a considerable quantity of *nitrogen*.

DR. RICHARD HANITSCH has been appointed Curator of the Raffles Museum at Singapore. Dr. Hanitsch has occupied for some years the post of Demonstrator of Zoology in University College, Liverpool, and is the author of a number of useful papers on the British Sponges.

THE third centenary of Christian Huygens will shortly be reached; for that celebrated Dutch physicist, astronomer, and mathematician died at the Hague on June 8, 1695. His investigations have been reviewed at length in these columns during recent years, and *Die Natur* for April 21 contains a notice concerning them.

The specimen of the Great Auk, to which we referred in these columns last week, has been sold to the Edinburgh Museum for £350.

Dr. Gordon E. Moore, well-known as a chemist, died at New York on April 16. Prof. Gustav Hirschfeld, a distinguished archæologist, has just died at Wiesbaden. We also notice the death of Prof. K. Thiersch, Professor of Surgery in Leipzig University.

Prof. Lloyd Morgan will lecture on "Habits of Birds," at the Royal Victoria Hall, Waterloo Bridge Road, on May 7. Other science lectures to be given during this month are: "Electric Tram Cars," by Dr. J. A. Fleming, F.R.S.; "The History of a Myth," by Prof. Sollas, F.R.S.; and "The Life of a Star," by Dr. A. Fison.

Gilbert White's original manuscript of the "Natural History of Selborne," in the form of letters to Thomas Pennant and Daines Barrington, first printed in 1789, was sold by auction last week by Messrs. Sotheby, Wilkinson, and Hodge. The manuscript contains many passages not printed in the several editions of the book, and has never been out of the possession of the lineal descendants of the author. It was bought by Mr. Pearson for £294.

The *Weekly Weather Report* of April 27 shows that some very heavy falls of rain occurred during the week; in nearly all districts amounts of an inch or upwards were measured, while over the greater part of England the fall was more than double the mean. But the amount of rainfall since the beginning of the year is still below the average, except in the north-east of England. The greatest deficiency is in the west of Scotland, where it amounts to about seven and a half inches.

The startling advance in market price of petroleum gives interest to the question of exhaustibility of the supply, following close upon the great decrease in supply of natural gas. In the height of the natural gas excitement, the warning of science was too little heeded, and lavish waste hastened the collapse. In 1887 the atmosphere of Pittsburgh was wonderfully clear, owing to the use of this new fuel; but Pittsburgh is again begrimed and sooty.

At the annual meeting of the National Academy of Sciences, recently held at Washington, Prof. Marsh, who has been president for several terms, was succeeded by Prof. Wolcott Gibbs, of Cambridge, who was elected for the ensuing term of six years, while Prof. Asaph Hall was re-elected home secretary. Prof. Alexander Agassiz is foreign secretary, and the members of the Council elected are Profs. George J. Brush, Othniel C. Marsh, Benjamin A. Gould, George H. Goodale, Simon Newcomb, and Ira Remsen.

A three days' conference on sanitary progress and reform was held at Manchester last week. A meeting introductory to the conference was held in the museum of Owens College, at which Prof. Boyd Dawkins delivered an address on prehistoric traces of sanitation. At the annual meeting of the Manchester and Salford Sanitary Association, in connection with which the conference was held, it was resolved that a Smoke Abatement League should be formed. Sir H. Roscoe, who afterwards took the chair at the conference session, pointed out that though attention was paid to the smoke from factory chimneys and from manufacturing operations, the larger question of the smoke from ordinary household fires was often neglected.

A very serious disaster is reported from France. A dam holding in check an immense reservoir of the Eastern Canal at Bousey, near Epinal, broke down on Saturday morning for a distance of some 300 feet. The torrent of water thus set free swept through Bousey, Avière, Uxegney, and Sanchey, carrying all before it, and washed away portions of the railway lines of Jussey and Nancy. Many bridges were carried away, and a great number of people were drowned. The Bousey reservoir (says the Paris correspondent of the *Times*) contained seven million cubic metres of water. The dam, which was constructed between 1879 and 1884, and was strengthened in 1888-89, was 60 feet thick at the base, and the foundation is laid in sandstone. According to a report sent out by the Minister of Public Works, there have never been any signs of weakness in the structure. Attempts are being made to throw the responsibility for the accident upon the engineers who superintended the strengthening of the dam six years ago.

A number of interesting objects obtained during the excavations of the Roman city at Silchester are on view at the Society of Antiquaries. During the past five years, the excavations have been carried on by Messrs. St. John Hope, Fox, Jones, and Stephenson, and some very valuable results were obtained last year. Twelve rectangular enclosures or buildings were found, all of the same type, and containing furnaces obviously of an industrial character and of various sizes, some of them being circular and others oblong. It is believed that these buildings and their adjuncts were devoted to the dyeing industry, and this conjecture is made probable by the large number of wells discovered, one of which was of peculiar and unusual construction. The circular furnaces correspond exactly with a dyeing furnace at Pompeii. They were, there is every reason to believe, used for dyeing. But there are a number of other furnaces with a straight flue, which are supposed to have been intended for drying. There are also traceable several rooms which, it is presumed, were intended for the storage of goods and materials, and open spaces with no remains of flues which may have been used for bleaching grounds. A number of querns for hand-grinding the madder-roots used for dyeing purposes have also been discovered.

The sixty-sixth anniversary meeting of the Zoological Society was held on Tuesday, with the President, Sir William H. Flower, K.C.B., F.R.S., in the chair. Dr. P. L. Sclater, F.R.S., read the report of the Council, in which it was announced that the silver medal of the Society had been awarded to Mr. Henry H. Johnston, C.B., H.M. Commissioner for British Central Africa, for his distinguished services to all branches of natural history by his collections made in Nyasaland, which had been described in the Society's *Proceedings*. The total receipts of the Society for 1894 amounted to £25,107 0*s.* 7*d.* The number of visitors to the Gardens during the year was 625,538, the corresponding number in 1893 having been 662,649; the decrease in the number of entrances (37,111) being due to the unfavourable weather of 1894. The number of animals in the Society's collection on December 31 last was 2563, of which 669 were mammals, 1427 birds, and 467 reptiles. Amongst the additions made during the past year, eleven were specially commented upon as of remarkable interest, and in most cases representing species new to the Society's collection. Among these were two remarkably fine specimens of the Hamadryad snake, a young white-tailed gnu (born in the Gardens), an eland of the striped form from the Transvaal (obtained by purchase), two giant tortoises, a young male Pleasant antelope, 2 Somali ostriches of the blue-skinned variety, 10 Surinam water-toads, a Pel's owl, and 2 tree kangaroos. About 30 species of mammals, 12 of birds, and 1 of reptiles had bred in the Society's Gardens during the summer of 1894. The Right Hon. George Denman, F. Du Cane Godman, F.R.S., Sir Hugh Low, G.C.M.G., Dr. St. George Mivart, F.R.S., and Osbert Salvin, F.R.S., were elected into the Council in the place of the retiring members, and Sir William H. Flower was re-elected President,

Charles Drummond, Treasurer, and Dr. Sclater, Secretary, to the Society for the ensuing year.

The first of the two conversaziones held at the Royal Society every year, takes place as we go to press. Annual receptions and exhibits, conducted upon much the same lines, are gradually being instituted by learned societies in various parts of the world. The New York Academy of Sciences recently held a similar exhibition, at which five hundred different objects of scientific interest were shown. From a report in the *Scientific American*, it appears that many of the exhibits were of a very striking character. A number of photographs of comets, of the Milky Way, and of star spectra, were shown by Profs. Barnard and Keeler, of the Lick and Allegheny Observatories. One of the most novel exhibits in physics, was a series of Chladni figures, shown by Prof. Alfred M. Mayer. The figures were formed in white sand upon vibrating metallic plates. Prof. Mayer's process consisted in fixing the sand upon a black background after the figures had been formed, by means of a fixative spray. These plates demonstrated the truth of Lord Rayleigh's theoretical deductions, and differed radically from all figures which are shown in text-books in the fact that none of the lines intersect. The physical exhibit was an extensive one, including a large number of instruments for spectroscopic, as well as for sound and light, measurements. The mineralogical exhibit included about one hundred objects. Biology was represented by preparations of nerve cells from the brain and spinal cord, by Prof. Golgi's method; and there were also shown several series of similar pictures bearing upon problems of inheritance, both in animals and plants. Bacteriology, mechanics, physiology, experimental psychology, anatomy, geology, and palæontology all took part in the exhibition. In vertebrate palæontology, the main exhibit was that showing the evolution of the horse. The series connecting the oldest known horse of the Lower Eocene period with the modern horse was probably the most complete which has ever been brought together. The little four-toed horse, recently acquired by the American Museum of Natural History from the collection of Prof. Cope, of Philadelphia, was exhibited. Although fully matured, it is only $3\frac{1}{2}$ hands high. The skull and limbs, nevertheless, display the characteristics of the horse. The teeth are short and simple; the limbs are scarcely larger in diameter than a good-sized pencil, and there are four toes, all resting upon the ground, in the fore-foot. A remarkable series of feet was also exhibited, giving all the stages between this four-toed horse and the modern one-toed animal. The reception at which the exhibits were shown was so successful that it has been decided to hold a similar one every year.

Dr. Bertram Windle contributes a paper to the *Journal of Anatomy and Physiology*, "On the effects of Electricity and Magnetism on development." The observations recorded were made on developing silkworms, trout, and chick embryos. In the case of the chick, the number of abnormally developed embryos was much greater in eggs incubated around the poles of a strong magnet than usual. With one exception all the malformations were associated with deficient development of the medullary area. Dr. Windle has not conclusively shown that this large proportion of abnormal embryos was actually due to the presence of the magnet, yet his results on the whole agree with those of Maggiorani, although certain points of difference were observed in the deformed embryos. The eggs of the silkworm moth were found to develop quite normally in a strong magnetic field. An electric current passing through a tank in which trout ova had been placed, seemed to produce an arrest of development. Dr. Windle concludes from his own observations and those of other authors, "that electricity produces an arresting effect upon development," while it is "very doubtful whether a magnetic field has any definite effect upon development or not."

A recent number of *Comptes rendus* contains an interesting paper by M. Branly, on the rate of loss of an electric charge due to the effect of light in the case of badly-conducting bodies. When the source of illumination is a body heated to a dull red, it is the condition of the illuminating surface which plays the chief part in the phenomenon. The nature of the charged body seems to have no effect. In the case where the illumination is rich in highly refrangible rays, however, the case is quite different, and the chief results obtained are as follows:—A disc of wood or marble, polished or unpolished, shows a marked loss of electricity when illuminated. If the disc is negatively electrified, the loss is more rapid than if it is positively electrified; but the difference is very much less marked than is the case with metal discs, particularly if they are polished. Similar results are obtained with cardboard, terra-cotta, and glass heated to 100°. The loss of a positive charge is rapid, while that of a negative one is slow in the case of varnished wood, or wood coated with a thin layer of oil, paraffin or tallow. With a metal disc coated with tallow, the loss when negatively electrified is slow, while the loss when positively electrified is very rapid. If a disc of polished wood, in which the loss of a negative charge is more rapid than that of a positive one, though the difference is not very marked, has the surface covered with a thin coating of plumbago, the loss with a negative charge becomes much more rapid than with a positive one. A metal plate covered with grease only loses a negative charge very slowly, the rate of loss of a positive charge being rapid. If, however, a thin coating of copper filings is spread over the tallow by means of a sieve, the loss with a positive charge becomes much more rapid than with a negative one. If powdered aluminium is used in the place of copper, the rates of loss in the case of positive and negative charges become nearly equal.

The United States Department of Agriculture publishes, in *Bulletin* No. 6 of the Department of Vegetable Pathology, a detailed paper, by Mr. D. G. Fairchild, on the use of "Bordeaux Mixture," a preparation of copper sulphate and lime, as a fungicide; and the mode of treatment of a number of diseases of fruit-trees, corn-crops, and garden plants caused by fungi.

The ninth edition has just been issued of part 1 of the *London Catalogue of British Plants*, comprising the Phanerogamia, Filices, Equisetaceæ, Selaginellaceæ, Marsileaceæ, and Characeæ. The changes introduced in this edition represent the results of the field-work, the critical study of British plants, and the researches on nomenclature, made during the last nine years. It is now edited by Mr. F. J. Hanbury.

The part of the *Agricultural Gazette of New South Wales* for January 1895 is chiefly occupied by papers on practical agriculture and breeding. Four species of so-called mahoganies of New South Wales are described by Mr. J. H. Maiden, all species of *Eucalyptus*. The life-history of the *Phylloxera vastatrix*, and the injuries inflicted by it on the vine, are described at length by Mr. J. A. Despeissis, and are illustrated by a coloured plate and numerous woodcuts.

With the title *Allgemeine botanische Zeitschrift für Systematik, Floristik, und Pflanzengeographie*, a new monthly botanical journal has been started at Carlsruhe, under the editorship of Herr A. Kneucker. Its aim is especially to deal with the study of difficult groups of plants, diagnoses of species, critical forms and hybrids, geographical botany, and the results of the travels of botanists.

In the *Bulletin* No. 9 of the *Minnesota Botanical Studies* is an interesting article by Mr. A. P. Anderson, on the Grand Period of Growth in the Fruit of *Cucurbita pepo*. From the time of fertilisation to that of ripening, the development may be divided into three periods—a period of active and continuous increase

from the time of pollination to the grand maximum; one of decline in the daily increase and rise in the daily decrease from the grand maximum to the beginning of ripening; and the ripening period. During this latter period an extended decrease, due to transpiration, lasting throughout the daily hours, was quickly followed by the maximum increase. At the time of the grand maximum the fruit gained 782 grammes in weight during twenty-four hours. The variations in length of the internodes occurred simultaneously with corresponding increase and decrease in the weight of the fruit.

THE Natural History Museum acquired last year some very remarkable corals, the largest weighing as much as fifteen hundred pounds. Two of these specimens have furnished Prof. Jeffrey Bell with subject for a note "On the variations observed in large Masses of *Turbinaria*," in the April *Journal* of the Royal Microscopical Society. The note is accompanied by two plates reproduced from photographs, and the point to which it directs attention is the considerable difference in size and form of the calicles in different portions of the same mass of coral. The plates show totally distinct forms comparatively close to one another, though the large mass, of which they represent parts, may be taken to be formed by a single species—*Turbinaria mesenterina*. The variability may, Prof. Bell points out, partly account for the difficulty which all students of corals have in determining specimens of the genus *Turbinaria*.

A YEAR ago the Board of Trinity College, Dublin, deposited in the Dublin Science and Art Museum the collection of weapons, &c., chiefly from the South Sea Islands, in their possession. A catalogue of the collection has now been prepared and published, with an introduction by Dr. V. Ball, the Director of the Museum. The collection has been known by common tradition as the "Cook Collection"; but a careful search has failed to bring to light direct evidence that the objects were really sent home by Captain Cook, though some of them are identical with objects figured in "Cook's Voyages." There is little doubt, however, about the reality of the association of the objects with the voyage, for the Minutes of the Board of Trinity College record that they were presented to the College in 1777 by Dr. Patten, who has been identified as the surgeon of the *Resolution* during Cook's second voyage. Part of the collection appears to have reached the College through the relatives of Captain King, who brought home the *Resolution* and *Discovery* after Captain Cook had been murdered. A brief statement as to other museums where collections of Cook's weapons are preserved, is given by Dr. Ball in the introduction to the catalogue. It is stated that in Great Britain the British Museum collection is the best in the world. Next to it in importance, in England, comes the collection in the Pitt-Rivers Museum. The Hunterian Museum in Glasgow University also contains some specimens, but how many is uncertain. So far as Dr. Ball has been able to ascertain, the museums on the continent which possess Cook collections are, arranged alphabetically, at Berne, Florence, Göttingen, Lausanne, Munich, Stockholm, and Vienna.

MESSRS. WILLIAM WESLEY AND SON have issued a very full catalogue of works on geology, offered for sale by them. The catalogue contains classified titles of more than two thousand different volumes, memoirs, and separate papers of interest to geologists. R. Friedländer and Söhn, Berlin, have sent us Nos. 1-5 of this year's *Naturae Novitates*. Bibliographers well know that the lists form a good index to current scientific literature. We have also received a catalogue, from Felix L. Dames, Berlin, containing titles of works on the invertebrates.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. Julius Scovell; a Pig-tailed Monkey (*Macacus nemestrinus*, ♀) from Sumatra, presented by Mr. D. Orville B. Dawson; three Maholi Galagos (*Galago maholi*) from South Africa, presented by Miss Van Beren; a Crowned Hawk Eagle (*Spizaetus coronatus*) from South Africa, presented by Dr. Schinland; an Antipodes Island Parrakeet (*Cyanorhamphus unicolor*) from Antipodes Island, New Zealand, presented by Sir Walter L. Buller; a Leopard Tortoise (*Testudo pardalis*), a Cape Viper (*Causus rhombeatus*) from South Africa, presented by Mr. J. E. Matcham; three Green Lizards (*Lacerta viridis*) from Jersey, presented by Masters J. S. and A. H. Hills; a Common Viper (*Vipera berus*) from Hampshire, presented by Mrs. P. C. Mitchell; two Angora Goats (*Capra hircus*, var.), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

SATURN'S RINGS.—In a recent communication to the Royal Astronomical Society, Prof. Barnard states that his measurements of the rings of Saturn show that no changes have taken place since the first systematic measures were made, and that there is no ground for the supposition that the rings are closing in upon the planet.

SEARCH EPHEMERIS FOR COMET 1884 II.—Dr. Berberich gives the following search ephemeris for Barnard's periodic comet of 1884 (*Ast. Nach.* 3260):

	R. A. h.	m.	s.	Decl. °	′
May 2	22	5	36	−18	24
10		35	16	15	38
18	23	3	54	12	40
26		31	20	9	35
June 3		57	26	6	27
11	0	22	7	3	22
19		45	20	−0	24
27	1	6	59	+2	25

The positions are for Berlin midnight, and the probable error amounts to 20m. in R.A. and 3° in decl. The comet passes from Aquarius to Cetus early in June, and remains in that constellation throughout the month. It must be looked for before sunrise.

THE HAMBURG OBSERVATORY.—From the report of the Hamburg Municipal Observatory we learn that the chief astronomical researches during 1894 had to do with the movements of comets and minor planets, and with the changes in variable stars of long period. Two memoirs of some importance have also been published (*Mitt. der Hamburger Sternwarte*, Nos. 1 and 2, 1895). The first of these is a catalogue of the positions of 105 nebulæ and star-clusters, reduced from observations made in the period 1871–1880, by Dr. Pechüle and the present director, Prof. G. Rümker. The positions have been deduced from micrometric measures in relation to known comparison stars, and are tabulated for the epoch 1875. Comparisons are made with the results of other observers, and, considering the difficulties attending the observations, there is a good all-round accordance of results; but it seems yet too early to expect much information with regard to proper motions. The second memoir is an investigation by Dr. Carl Stechert of the orbit of the minor planet Tycho (258) and of the perturbations produced by Jupiter and Saturn. It is shown that the probable apparent semi-diameter of the planet at opposition is about 0″·05, the true semi-diameter being something between 50 and 80 kilometres. An ephemeris is given for observations during the opposition of June 20, 1895.

THE LATE M. TROUVELOT.—By the death of M. L. Trouvelot, on April 22, observational astronomy has lost one of its foremost workers. M. Trouvelot was born at Guyencourt, in 1827, and after the *coup d'état*, he went to Cambridge, U.S.A., where he lived until 1882. His first published works, which appeared in 1866, were on natural history subjects; later he became an astronomer at the Harvard College Observatory, and commenced the observations of the sun and planets which have made his name known to all students of celestial science. Shortly after the Meudon Observatory was founded, he returned to France, and has since then carried on his work in it. Trouvelot's important observations of the planet Venus, published in 1892, are still fresh in the minds of astronomers. He also paid attention to the planets Jupiter and Saturn. His beautiful drawings of celestial objects and phenomena observed by him are to be found in many works on astronomy.

THE SUN'S PLACE IN NATURE.[1]

V.

AT the end of the last lecture we arrived at that point of our inquiry which is connected with the possible first stage of all cosmical bodies, and we saw that there was a considerable amount of evidence in favour of the idea that in this first stage all cosmical bodies are not masses of hot gas, but that their temperature is low.

Continuing this inquiry in the light of the suggestion that the first stage might be connected with swarms of meteorites, we found the great probability that, in swarms or streams of meteorites, or meteoritic dust, we had to deal with the real basis of all cosmical bodies.

Now, if we take the heavens as we find them, whether we deal with stars, secondary bodies, or satellites, we find that they are all in movement, and it therefore follows that in these earliest stages with which we have now to deal, whether they were meteoritic swarms or streams, they were also in movement. I have already taken an opportunity of pointing out to you how very important these considerations are when we come to inquire into the constitution of each nebula. I showed you in the last lecture a beautiful photograph (Fig. 7, vol. li. p. 397), taken by Dr. Roberts, of the spiral nebula in one of our northern constellations, and I now propose to show you another very similar to it, in order, if I can, to bring more closely before you certain of the facts which were then indicated. In this wonderful photograph of the nebula in Andromeda we are undoubtedly dealing with streams, and the movements towards the centre are all along spirals. In the case of the other nebula we were in a better condition for observing the actual direction of motion because we were looking down on the system, we got a section in the plane of movement; but we are looking at this nebula in an inclined direction, though I think you will still have no difficulty in seeing that the various streams round the centre of condensation are all of them of a spiral form, with certain condensations interspersed here and there along them.

Fig. 2.—The Great Nebula in Andromeda, from a photograph by Dr. Roberts.

We have a condensation in the prolongation of one of the spirals, and there is considerable clustering of apparent stars along those lines, which I ventured in my last lecture to call stream lines, for the reason that I was anxious to indicate that we had in these appearances, not signs which told us of the existence of matter—so that when you have not the appearances you would be justified in supposing that there was no matter—but an indication of movement in matter, so that we may imagine that this nebula and others like it do probably consist of a swarm of meteorites, extending enormously in space beyond the indications which you see, for the reason that towards the centre the movements will be more violent than they are towards the outside. We are there face to face with the idea that we have to deal with orderly movements of meteoritic masses. Now, let me call your attention to this fact. If the movements are orderly, it means that the movements of the constituent particles of the swarm, all of them, or most of them, will be in the same direction: that in that case you have the condition of minimum disturbance, and therefore the condition of minimum temperature.

We can pass from such a nebula as this to the well-known planetary nebulæ. Almost all the knowledge which we have of these nebulæ we owe to the labours of Sir William and Sir John Herschel. You will see that so far as appearance goes, we have in these planetary nebulæ almost to deal with a planet like Jupiter, except that we do not see the belts. That is why these bodies are called planetary nebulæ; they give us the idea that we are dealing with discs. If we pass for a moment from a nebula which is simply discoidal to one such as is represented in another part of the diagram, you find there that we get a very faint disc, including much brighter condensation at the centre. If you look at the others, you will find that we get a very obvious condensation towards the centre; there is a very considerable difference in the intensity of the light given out as the centre is approached.

Of course we understand that if in these, also, the movements are quite orderly, we must not expect to get any very great disturbance, and therefore—if these disturbances produce high temperatures—we shall not expect to get indications of any particularly high temperatures from their external portions.

Dealing with nebulæ, then, as a whole, it does not seem too much to say that we are justified in supposing that they may advance towards condensation along two perfectly distinct roads. If we consider a regular spiral nebula, like the one in Andromeda, or a planetary nebula, we may imagine them living their life as nebulæ without very much disturbance; there is not much fighting to be done, they progress in orderly fashion towards the condition of complete condensation at the centre.

But there is another way.

In the nebula of Orion we get absolute absence of anything like regularity. In any part where the structure can be studied, we find it consists of whirls and streams crossing each other, some of them straight, some of them curved, the whole thing an irregular complicated mixture of divergent movements, so far as the photographs, which are absolutely untouched, can give us any idea of what is going on. Take, for instance, the magnificent streamer trending upwards. It gradually becomes brighter until it reaches one of the brightest parts of the nebula; and observe, also, the stars which seem dotted over it as on a shield. It is quite obvious that we cannot, in such a structure as that, expect to get the same conditions that we met with in the nebula of Andromeda, and in the planetary nebulæ. And, in fact, we do not. In this nebula, which speaks of disturbance in every inch of it, we have spectroscopic indications of very high temperature indeed. Carbon is replaced by hydrogen. In such a nebula as this, it is impossible for us to pick out the place of condensation; the condensation may be held to be anywhere, for disturbances are obviously everywhere. And you remember, I hope, that I pointed out to you that the part of

[1] Revised from the [illegible] of [illegible] Lectures to Working Men at the Museum of Practical Geology during November and December 1894. (Continued from [illegible].)

the nebula ordinarily seen is but the brightest part of a nebula extending over a space in the surrounding neighbourhood, which recent research shows is scarcely limited to the whole constellation.

Now, it so happens that the spectrum of the nebula of Orion has recently been very carefully studied from the point of view of the chemical substances which may be building up this special spectroscopic type. Here is a photograph of a part of the spectrum of the nebula of Orion; and I may tell you that it is a very difficult thing to obtain a photograph of such a very feeble light source. It is a copy of a photograph which was exposed for something like three hours at the focus of a 30-inch mirror of short focus; and in copying it we lose a great deal of the detail, a great many of the lines which are recorded by Dame Nature herself in what we call the negative. The negative

FIG. 23.—The Great Nebula in Orion, from a long exposure photograph by Dr. Roberts.

contains something like fifty lines, which have already been measured; but in the attempt to enlarge, a great many of these have been left behind.

You will see, however, without any difficulty, that the spectrum shows many bright lines; that being so, an attempt has been made to determine the positions of all of them. The result is really extremely interesting. We find, in fact, that there may in all probability be three perfectly different sources of the bright lines which, taken together, build up the so-called spectrum of the nebula. In the first place, I showed you that when we experiment with meteoritic dust in our laboratories, it has not been subjected to a low pressure very long before it begins to give out certain compounds of carbon, mingled with hydrogen gas, and we find that in the nebula of Orion we really do get indications of gaseous compounds of carbon, and also of the gas hydrogen. In order to make the distinction perfectly clear between the two other possible sources of nebula lines, let me ask you for one moment to conceive yourselves in the middle of the gigantic battle which is going on between meteoritic particles in such a nebula as that of Orion. You have particles rushing together in all possible directions, particles, no doubt, different in origin. You will expect, among those millions and billions and trillions of collisions, to get a very considerable number of grazes; and the whole point of collisions among physical particles is that, if two things go straight at each other, you get what you may call an end-on collision, which may be bad for one or both of the bodies concerned; physically we may say the temperature under these circumstances is at a maximum. But you will understand that the number of grazes, or near misses, must be very much greater than the number of end-on collisions; in such a case as we are imagining, there will be an immense number of grazes. What will a graze do? It is simply a slight collision; the amount of temperature developed by it will be small; we shall therefore get the production of vapours at a low temperature, and if we get any luminous effect at all, it will be one proper to the vapours at low temperature. So that on first principles we should expect in such a nebula as the one we are discussing to get a very large number of grazes, giving us low temperature effects, and a very much smaller number of end-on collisions, giving us very high temperature effects. Now, what are the facts? We say the most numerous collisions are partial ones, grazes. Well, there is the fluting, most probably due to magnesium at λ500, and that fluting of magnesium is the lowest temperature indication of the existence of magnesium; if magnesium becomes luminous at all by virtue of its temperature, one of the first things revealed to us spectroscopically is the particular fluting in question. We may also note the longest lines seen in the oxy-hydrogen flame of iron, calcium and magnesium as well. Those lines we are justified in considering as indications of an enormous number of grazes among these meteoritic particles. But that is not all. Going further, we find that there will be a small number of end-on collisions giving us the highest possible temperature. Being students of science, we are of course anxious to know what conditions are present in a case of that kind; that is, we want to know what the possible results of the highest temperature will be. The natural thing, I think, is to go to the sun, which is pretty hot, and then find out the very hottest place, which we can do by means of our spectroscopes, and then study very carefully, for years even, the spectroscopic indications in that particularly hottest place of the nearest star which we can get at. I hope you will acknowledge that that is a philosophic way of going to work. Thus we are landed in what is called the chromosphere of the sun. The upper atmosphere of the sun must be rapidly cooling, but the chromosphere is a thin envelope some 5000 or 10,000 miles thick, just outside the photosphere, agreed to be the hottest part of the sun within our ken, and therefore any lines which we see special to that region are called chromospheric lines, and they should be proper to high temperatures.

The chromospheric line D_3 represents a line near the sodium line D in the solar spectrum, which with a few others has the proud pre-eminence of nearly always being bright: hence we suppose that we have something hotter than anything else which exists at the exterior level of the solar photosphere. Running in couples with this line D_3 there is another in the blue part of the spectrum, represented by a certain wave-length (4471) which behaves always in the same way, *i.e.* it is almost always seen very bright, and it is never seen dark among the Fraunhofer lines in the solar spectrum. From the solar point of view then, as the sun is a thing that we can get at better than any of the other stars, because it is so near to us, a mere trifle of 90 millions of miles or so, we are justified in saying that these two lines represent, in fact, the spectrum of the hottest part of space about which we can be absolutely certain. Hence it is very interesting to inquire whether or not these two lines exist in the nebulæ as representing the high temperature results of end-on collisions.

They do exist in nebulæ, and in some of them they are among the most striking indications in the spectrum.

So that we find in the spectrum of the nebula of Orion, when it is carefully studied, indications of the gases which are known to be occluded in meteorites, and which are perfectly prepared to come out of them the moment you give them the least

chance. Then, also, there is the indication of the results of an infinitely great number of grazes in the shape of lines of metals which we see at the temperature of the oxy-hydrogen flame, but which we do not see so well at the temperature of the arc and the spark; and, on the other hand, there are indications of the results of high temperature which we can study in the sun, and such obvious indications of high temperature that we get the two lines which I have referred to, neither of which has ever been seen so far in any terrestrial laboratory, although they are very familiar indeed to students of solar physics.

The total result of all this inquiry has been that the mean temperature of the meteoritic phenomena brought before us by the nebula of Orion is distinctly low. That is a result of extreme interest and importance, because, remembering what was said about the objection to Laplace's view of high temperature gas because it violated the laws of thermodynamics, we have now, after minute study, come to a conclusion regarding the structure of these nebulæ, which is quite in harmony with the laws of thermodynamics.

When the series of lines associated with high temperatures was first recorded in the spectrum of the nebulæ, I stated that possibly this might be due to the fact that in regions of space where the pressure always operative is extremely low, we might be in the presence of chemical forms which are unfamiliar to us here, because all that we know of here chemically is the result probably of considerable temperature, and not very low pressure. It was therefore supposed that these lines might represent to us the action of unfamiliar conditions in space. Thus, if we have a compound chemical substance, and increase its temperature sufficiently, the thing goes to pieces—is dissociated; but imagine a condition of things in which we have that same chemical substance for a long time exposed to the lowest possible pressure. Is it possible that that substance will ever get pulled to bits? If so, we may imagine parts of space which will contain these substances pulled to bits which really constitute finer forms of matter than our chemical substances. So that we may logically expect to get the finest possible molecules as distinct entities in the regions where the pressure is the lowest possible. These forms are, of course, those we should expect to be produced by a very high temperature brought on by end-on collisions; hence the line of thought is not greatly changed in both these explanations, and I think that probably future research may show that we are justified in looking to both of these possible causes as those which produce for us those so-called "chromospheric lines" which we find in the spectrum of the nebulæ.

However that may be, we have arrived finally at the conclusion that the temperature of these nebulæ is low on the meteoritic hypothesis.

I have already referred in my previous lectures to Dr. Huggins's views connected with the nebulæ and stars, and you will therefore quite understand that I am delighted to find that Dr. Huggins has now come to the conclusion that in nebulæ we have distinctly a relatively low temperature. In 1889 Mr. Huggins wrote:[1] "They [the nebulæ] consist probably of gas at a high temperature," but in the address of 1891, to which I have already had occasion to refer, he gives this view up, and refers to "the much lower mean temperature of the gaseous mass *which we should expect at so early a stage of condensation*!"[2]

I am also glad to say that Dr. Keeler is also perfectly prepared to accept the view I have been insisting on. So that, if the opinion of astronomers of repute is worth anything, we do seem to have arrived at very solid ground indeed on this point, so far as consensus of opinion can make any ground solid.

J. Norman Lockyer.

(*To be continued.*)

THE RARER METALS AND THEIR ALLOYS.[3]

THE study of metals possesses an irresistible charm for us, quite apart from its vast national importance. How many of us made our first scientific experiment by watching the melting of lead, little thinking that we should hardly have done a bad life's work if the experiment had been our last, provided we had only understood its full significance. How few of us forget that we wistfully observed at an early age the melting in an ordinary fire of some metallic toy of our childhood; and the experiment has, like the "Flat iron for a farthing," in Mrs. Ewing's charming story, taken a prominent place in literature which claims to be written for children. Hans Andersen's fairy tale, for instance, the "History of a Tin Soldier," has been read by children of all ages and of most nations. The romantic incidents of the soldier's eventful career need not be dwelt upon; but I may remind you that at its end he perished in the flames of an ordinary fire, and all that could subsequently be found of him was a small heart-shaped mass. There is no reason to doubt the perfect accuracy of the story recorded by Andersen, who at least knew the facts, though his statement is made in popular language. No analysis is given of the tin soldier; in a fairy tale it would have been out of place, but the latest stage of his evolution is described, and the record is sufficient to enable us to form the opinion that he was composed of both tin and lead, certain alloys of which metals will burn to ashes like tinder. His uniform was doubtless richly ornamented with gold lace. Some small amount of one of the rarer metals had probably—for on this point the history is silent—found its way into his constitution, and by uniting with the gold, formed the heart-shaped mass which the fire would not melt, as its temperature could not have exceeded 1000°; for we are told that the golden rose, worn by the *artiste* who shared the soldier's fate, was also found unmelted. The main point is, however, that the presence of one of the rarer metals must have endued the soldier with his singular endurance, and in the end left an incorruptible record of him.

This has been taken as the starting-point of the lecture, because we shall see that the ordinary metals so often owe remarkable qualities to the presence of a rarer metal which fits them for special work.

This early love of metals is implanted in us as part of our "unsquandered heritage of sentiments and ideals which has come down to us from other ages," and future generations of children will know far more than we did; for the attempt will be made to teach them that even psychology is a branch of molecular physics, and they will therefore see far more in the melted toy than a shapeless mass of tin and lead. It is really not an inert thing; for some time after it was newly cast, it was the scene of intense molecular activity. It probably is never molecularly quiescent, and a slight elevation of temperature will excite in it rapid atomic movement anew. The nature of such movement I have indicated on previous occasions when, as now, I have tried to interest you in certain properties of metals and alloys.

This evening I appeal incidentally to higher feelings than interest, by bringing before you certain phases in the life-history of metals which may lead you to a generous appreciation of the many excellent qualities they possess.

Metals have been sadly misunderstood. In the belief that animate beings are more interesting, experimenters have neglected metals, while no form of matter in which life can be recognised is too humble to receive encouragement. Thus it happens that bacteria, with repulsive attributes and criminal instincts, are petted and watched with solicitude, and comprehensive schemes are submitted to the Royal Society for their development, culture, and even for their "education,"[1] which may, it is true, ultimately make them useful metallurgical agents, as certain micro-organisms have already proved their ability to produce arseniuretted hydrogen from oxide of arsenic.[2]

It will not be difficult to show that methods which have proved so fruitful in results when applied to the study of living things, are singularly applicable to metals and alloys, which really present close analogies to living organisms. This must be a new view to many, and it may be said, "it is well-known that uneducated races tend to personify or animate external nature," and you may think it strange that the attempt should be made to trace analogies which must appear to be remote, between moving organisms and inert alloys, but "the greater the number of attributes that attach to anything, the more real that thing is."[3] Many of the less known metals are very real to me, and I want them to be so to you; listen to me, then, as speaking for my silent metallic friends, while I try to secure for them your sympathy and esteem.

First, as regards their origin and early history. I fully

2 In this portion of the passage, the italics and notes of exclamation are mine.—J. N. L.

3 A Friday evening discourse, delivered at the Royal Institution on March [illegible], by Prof. Roberts-Austen, C.B., F.R.S.

1 Dr. Percy Frankland specially refers to the "education" of bacilli for adapting them to altered conditions. *Roy. Soc. Proc.*, vol. lvi., 1894, p. 539.

2 Dr. Brauner. *Chem. News*, Feb. 15, 1895. P. 79.

3 Lotze, "Metaphysic," § 1, quoted by Illingworth, "Personality, Human and Divine." Bampton Lectures, 1894, p. 43.

share Mr. Lockyer's belief as to their origin, and think that a future generation will speak of the evolution of metals as we now do of that of animals, and that observers will naturally turn to the sun as the field in which this evolution can best be studied.

To the alchemists metals were very living indeed; they treated them as if they were, and had an elaborate pharmacopœia of "medicines" which they freely administered to metals in the hope of perfecting their constitution. If the alchemists constantly draw parallels between living things and metals, it is not because they were ignorant, but because they recognised in metals the possession of attributes which closely resemble those of organisms. "The first alchemists were gnostics, and the old beliefs of Egypt blended with those of Chaldea in the second and third centuries. The old metals of the Egyptians represented men, and this is probably the origin of the *homunculu* of the middle ages, the notion of the creative power of metals and that of life being confounded in the same symbol."[1]

Thus Albertus Magnus traces the influence of congenital defects in the generation of metals and of animals, and Basil Valentine symbolises the loss of metalline character, which we now know is due to oxidation, to the escape from the metal of an indestructible spirit which flies away and becomes a soul. On the other hand, the "reduction" of metals from their oxides was supposed to give the metals a new existence. A poem[2] of the thirteenth century well embodies this belief in the analogies between men and metals, in the quaint lines:—

> "Homs ont l'estre comme metaulx,
> Vie et augment des vegetaulx,
> Instinct et sens comme les bruts,
> Esprit comme ange en attributes."

"Men have being" constitution like metals: you see how closely metals and life were connected in the minds of the alchemists.

"Who said these old renowns, dead long ago, could make me forget the living world?" are words which Browning places in the lips of Paracelsus, and we metallurgists are not likely to forget the living world; we borrow its definitions, and apply them to our metals. Thus nobility in metals as in men, means freedom from liability to tarnish, and we know that the rarer metals, like the rarer virtues, have singular power in enduing their more ordinary associates with firmness, elasticity, strength, and endurance. On the other hand, some of the less known metals appear to be mere "things" which do not exist for themselves, but only for the sake of other metals to which they can be united. This may, however, only seem to be the case because we as yet know so little about them. The question naturally arises, how can the analogies between organic and inorganic bodies be traced? I agree with my colleague at the École des Mines of Paris, Prof. Urbain le Verrier, in thinking that it is possible[3] to study the biology, the anatomy, and even the pathology of metals.

The anatomy of metals—that is, their structure and framework—is best examined by the aid of the microscope, but the method of autographic pyrometry, which I brought before you in a Friday evening lecture delivered in 1891, is rendering admirable service in enabling both the biology and pathology of metals to be studied, for, just as in biological and pathological phenomena vital functions and changes of tissue are accompanied by a rise or fall in temperature, so molecular changes in metals are attended with an evolution or absorption of heat. With the aid of the recording pyrometer we now "take the temperature" of a mass of metal or alloy in which molecular disturbance is suspected to lurk, as surely as a doctor does that of a patient in whom febrile symptoms are manifest.

It has, moreover, long been known that we can submit a metal or an alloy in its normal state to severe stress, record its power of endurance, and then, by allowing it to recover from fatigue, enable it to regain some, at least, of its original strength. The human analogies of metals are really very close indeed, for, as is the case with our own mental efforts, the internal molecular work which is done in metals often strengthens and invigorates them. Certain metals have a double existence, and, according to circumstances, their behaviour may be absolutely harmful or entirely beneficial.

[2] *Les Remonstrances ou la complaint de nature a l'alchimist errant.* Attributed to Jehan de Meung, who with Guillaume de Lorris wrote the *Roman de la Rose.* M. Méon, the editor of the edition of 1814 of this celebrated work, doubts, however, whether the attribution of the *complaint de nature* to Meung is correct.
[3] "La Metallurgie in France," 1894, p.

The dualism we so often recognise in human life becomes allotropism in metals, and they, strangely enough, seem to be restricted to a single form of existence if they are absolutely free from contamination, for probably an absolutely pure metal cannot pass from a normal to an allotropic state. Last, it may be claimed that some metals possess attributes which are closely allied to moral qualities, for, in their relations with other elements, they often display an amount of discrimination and restraint that would do credit to sentient beings.

Close as this resemblance is, I am far from attributing consciousness to metals, as their atomic changes result from the action of external agents, while the conduct of conscious beings is not determined from without, but from within. I have, however, ventured to offer the introduction of this lecture in its present form, because any facts which lead us to reflect on the unity of plan in nature, will aid the recognition of the complexity of atomic motion in metals upon which it is needful to insist.

The foregoing remarks have special significance in relation to the influence exerted by the rarer metals on the ordinary ones. With exception of the action of carbon upon iron, probably nothing is more remarkable than the action of the rare metals on those which are more common; but their peculiar influence often involves, as we shall see, the presence of carbon in the alloy.

Which, then, are the rarer metals, and how may they be isolated? The chemist differs somewhat from the metallurgist as to the application of the word "rare." The chemist thinks of the "rarity" of a compound of a metal; the metallurgist, rather of the difficulty of isolating the metal from the state of combination in which it occurs in nature.

The chemist in speaking of the reactions of salts of the rarer metals, in view of the wide distribution of limestone and pyrolusite, would hardly think of either calcium or manganese as being among the rarer metals. The metallurgist would consider pure calcium or pure manganese to be very rare, I have only recently seen comparatively pure specimens of the latter.

The metals which, for the purposes of this lecture, may be included among the rarer metals are: (1) those of the platinum group, which occur in nature in the metallic state; and (2) certain metals which in nature are usually found as oxides or in an oxidised form of some kind, and these are chromium, manganese, vanadium, tungsten, titanium, zirconium, uranium, molybdenum (which occurs, however, as sulphide). Incidental reference will be made to nickel and cobalt.

Of the rare metals of the platinum group I propose to say but little; we are indebted for a magnificent display of them in the library to my friends Messrs. George and Edward Matthey and to Mr. Sellon, all members of a great firm of metallurgists. You should specially look at the splendid mass of palladium, extracted from native gold of the value of £2,500,000, at the melted and rolled iridium, and at the masses of osmium and rhodium. No other nation in the world could show such specimens as these, and we are justly proud of them.

These metals are so interesting and precious in themselves, that I hope you will not think I am taking a sordid view of them by saying that the contents of the case exhibited in the library are certainly not worth less than ten thousand pounds.

As regards the rarer metals which are associated with oxygen, the problem is to remove the oxygen, and this is usually effected either by affording the oxygen an opportunity for uniting with another metal, or by reducing the oxide of the rare metal by carbon, aided by the tearing effect of an electric current. In this crucible there is an intimate mixture, in atomic proportions, of oxide of chromium and finely divided metallic aluminium. The thermo-junction (A, Fig. 1) of the pyrometer which formed the subject of my last Friday evening lecture here, is placed within the crucible, B, and the spot of light, C, from the galvanometer, D, with which it is connected, indicates on the screen that the temperature is gradually rising. You will observe that as soon as the point marked 1010° is reached, energetic action takes place: the temperature suddenly rising above the melting-point of platinum, melts the thermo-junction, and the spot of light swings violently; but if the crucible be broken open, you will see that a mass of metallic chromium has been liberated.

The use of alkaline metals in separating oxygen from other metals is well known. I cannot enter into its history here, beyond saying that if I were to do so, frequent references to

the honoured names of Berzelius, Wohler, and Winkler would be demanded.[1]

Mr. Vautin has recently shown that granulated aluminium may readily be prepared, and that it renders great service when employed as a reducing agent. He has lent me many specimens of rarer metals which have been reduced to the metallic state by the aid of this finely-granulated aluminium; and I am indebted to his assistant, Mr. Picard, who was lately one of my own students at the Royal School of Mines, for aid in the preparation of certain other specimens which have been isolated in my laboratory at the Mint.

The experiment you have just seen enables me to justify a statement I made respecting the discriminating action which certain metals appear to exert. The relation of aluminium to other metals is very singular. When, for instance, a small quantity of aluminium is present in cast-iron, it protects the silicon, manganese, and carbon from oxidation.[2] The presence of silicon in aluminium greatly adds to the brilliancy with which aluminium itself oxidises and burns.[3] It is also asserted that aluminium, even in small quantity, exerts a powerful protective action against the oxidation of the silver-zinc alloy which is the result of the desilverisation of lead by zinc.

Moreover, heat aluminium in mass to redness in air, where oxygen may be had freely, and a film of oxide which is formed will protect the mass from further oxidation. On the other hand, if finely divided aluminium finds itself in the presence of an oxide of a rare metal, at an elevated temperature, it at once acts with energy and promptitude, and releases the rare metal from the bondage of oxidation. I trust, therefore, you will consider my claim that a metal may possess moral attributes has

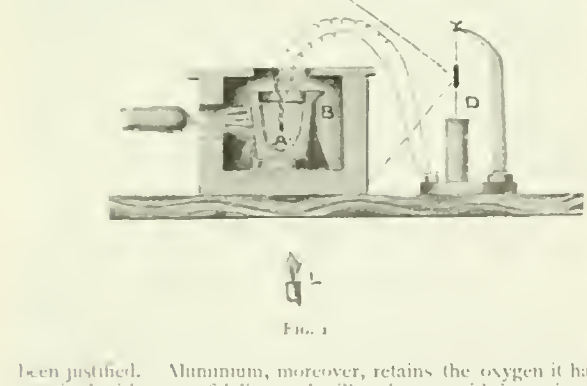

FIG. 1

been justified. Aluminium, moreover, retains the oxygen it has acquired with great fidelity, and will only part with it again at very high temperatures, under the influence of the electric arc in the presence of carbon.

[A suitable mixture of red lead and aluminium was placed in a small crucible heated in a wind furnace, and in two minutes an explosion announced the termination of the experiment. The crucible was shattered to fragments.]

The aluminium loudly protests, as it were, against being entrusted with such an easy task, as the heat engendered by its oxidation had not to be used in melting a difficultly fusible metal like chromium, the melting point of which is higher than that of platinum.

It is admitted that a metal will abstract oxygen from another metal if the reaction is more exothermic than that by which the oxide to be decomposed, was originally formed. The heat of formation of alumina is 391 calories, that of oxide of lead is 51 calories; so that it might be expected that metallic aluminium, at an elevated temperature, would readily reduce oxide of lead to the metallic state.

The last experiment, however, proved that the reduction of oxide of lead by aluminium is effected with explosive violence, the temperature engendered by the reduction being sufficiently high to volatilise the lead. Experiments of my own show that the explosion takes place with much disruptive power when aluminium reacts on oxide of lead *in vacuo*, and that if coarsely ground, fused litharge be substituted for red lead, the action is only accompanied by a rushing sound. The result is, therefore, much influenced by the rapidity with which the reaction can be transmitted throughout the mass. It is this kind of experiment which makes us turn with such vivid interest to the teaching of the school of St. Claire Deville, the members of which have rendered such splendid services to physics and metallurgy. They do not advocate the employment of the mechanism of molecules and atoms in dealing with chemical problems, but would simply accumulate evidence as to the physical circumstances under which chemical combination and dissociation take place, viewing these as belonging to the same class of phenomena as solidification, fusion, condensation, and evaporation. They do not even insist upon the view that matter is minutely granular, but in all cases of change of state, make calculations on the basis of work done, viewing changed "internal energy" as a quantity which should reappear when the system returns to the initial state.

A verse, of some historical interest, may appeal to them. It occurs in an old poem to which I have already referred as being connected with the *Roman de la Rose*, and it expresses nature's protest against those who attempt to imitate her works by the use of mechanical methods. The "argument" runs thus:—

> "Comme nature se complaint,
> Et dit sa douleur et son plaint,
> A ung sot souffleur sophistique,
> Qui n'use que d'art méchanique."

If the "use of mechanical art" includes the study of chemistry on the basis of the mechanics of the atoms, I may be permitted to offer the modern school the following rendering of nature's plaint:—

> "How nature sighs without restraint,
> And grieving makes her sad complaint
> Against the subtle sophistry
> Which trusts atomic theory."

An explosion such as is produced when aluminium and oxide of lead are heated in presence of each other, which suggested the reference to the old French verse, does not often occur, as in most cases the reduction of the rarer metals by aluminium is effected quietly.

Zirconium is a metal which may be so reduced. I have in this way prepared small quantities of zirconium from its oxide, and have formed a greenish alloy of extraordinary strength by the addition of $\frac{1}{10}$ per cent. of it to gold, and there are many circumstances which lead to the belief that the future of zirconium will be brilliant and useful. I have reduced vanadium and uranium from its oxide by means of aluminium as well as manganese, which is easy, and titanium, which is more difficult. Tungsten, in fine specimens, is also before you, and allusion will be made subsequently to the uses of these metals. At present I would draw your attention to some properties of titanium which are of special interest. It burns with brilliant sparks in air; and as few of us have seen titanium burn, it may be well to burn a little in this flame. [Experiment performed.] Titanium appears to be, from the recent experiments of M. Moissan, the most difficultly fusible metal known; but it has the singular property of burning in nitrogen—it presents, in fact, the only known instance of vivid combustion in nitrogen.[1]

Titanium may be readily reduced from its oxide by the aid of aluminium. Here are considerable masses, sufficiently pure for many purposes, which I have recently prepared in view of this lecture.

The other method by which the rarer metals may be isolated is that which involves the use of the electrical furnace. In this connection the name of Sir W. Siemens should not be forgotten. He described the use of the electric arc-furnace in which the carbons were arranged vertically, the lower carbon being replaced by a carbon crucible, and in 1882 he melted in such a furnace no less than ten pounds of platinum during an experiment at which I had the good fortune to assist. It may fairly be claimed that the large furnaces with a vertical carbon in which aluminium and other metals are now reduced by the combined electrolytic action and tearing temperature of the arc, are the direct outcome of the work of Siemens.

In the development of the use of the electric arc for the isolation of the rare, difficultly fusible, metals Moissan stands

[1] An interesting paper by H. F. Keller, on the reduction of oxides of metals by other metals, will be found in the *Journal* of the American Chemical Society, December 1894, p. [illegible].

[1] Lord Rayleigh has since stated that titanium does not combine with argon; and M. Guntz points out that lithium in combining with nitrogen produces incandescence.

in the front rank. He points out[1] that Deprez[2] used in 1849, the heat produced by the arc of a powerful pile; but Moissan was the first to employ the arc in such a way as to separate its heating effect from the electrolytic action it exerts. This he does by placing the poles in a horizontal position, and by reflecting their heat into a receptacle below them. He has shown, in a series of classical researches, that employing 800 amperes and 110 volts a temperature of at least 3500° may be attained, and that many metallic oxides which until recently were supposed to be irreducible may be readily made to yield the metal they contain.[3]

A support or base for the metal to be reduced is needed, and this is afforded by magnesia, which appears to be absolutely stable at the utmost temperatures of the arc. An atmosphere of hydrogen may be employed to avoid oxidation of the reduced metal, which, if it is not a volatile one, remains at the bottom of the crucible almost always associated with carbon—forming, in fact, a carbide of the metal. I want to show you the way in which the electric furnace is used, but unfortunately the reductions are usually very tedious, and it would be impossible to actually show you much if I were to attempt to reduce before you any of the rarer metals; but as the main object is to show you how the furnace is used, it may be well to *boil* some silver at a temperature of some 2500°, and subsequently to melt chromium in the furnace (Fig. 2). This furnace consists of a clay receptacle, A, lined with magnesia, B. A current of 60 amperes and 100 volts is introduced by the carbon poles, C, C′; an electro-magnet, M, is provided to deflect the arc on to the metal to be melted. [By

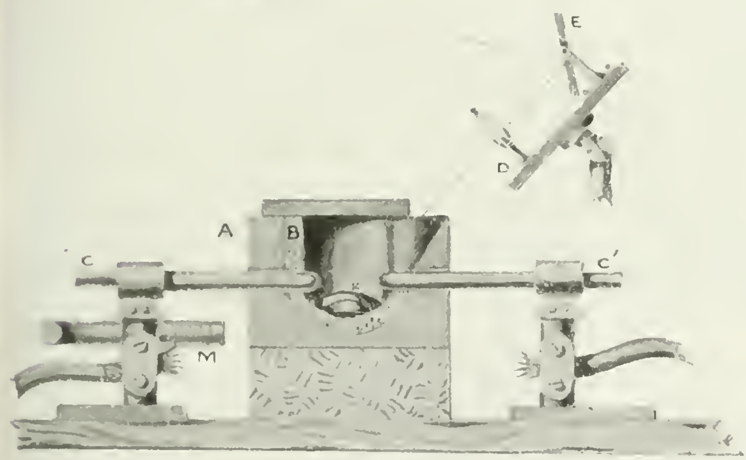

FIG. 2.

means of a lens and mirror, D, E, the image of the arc and of the molten metal was projected on to a screen. For this purpose it was found convenient to make the furnace much deeper than would ordinarily be the case.]

It must not be forgotten that the use of the electric arc between carbon poles renders it practically impossible to prepare the rare metals without associating them with carbon, often forming true carbides; but it is possible in many cases to separate the carbon by subsequent treatment. Moissan has, however, opened up a vast field of industrial work by placing at our disposal practically all the rarer infusible metals which may be reduced from oxides, and it is necessary for us now to consider how we may best enter upon our inheritance. Those members of the group which we have known long enough to appreciate are chromium and manganese, and these we have only known free from carbon for a few months. In their carburised state they have done excellent service in connection with the metallurgy of steel; and may we not hope that vanadium, molybdenum, titanium, and uranium will render still greater services? My object in this lecture is mainly to introduce you to these metals, which hitherto few of us have ever seen except as minute cabinet specimens, and we are greatly indebted to M. Moissan for sending us beautiful specimens of chromium, vanadium, uranium, zirconium, tungsten, molybdenum, and titanium. [These were exhibited.]

The question naturally arises: Why is the future of their usefulness so promising? Why are they likely to render better service than the common metals with which we have long been familiar? It must be confessed that as yet we know but little what services these metals will render when they stand alone; we have yet to obtain them in a state of purity, and have yet to study their properties, but when small quantities of any of them are associated or alloyed with other metals, there is good reason to believe that they will exert a very powerful influence. In order to explain this, I must appeal to the physical method of inquiry to which I have already referred.

It is easy to test the strength of a metal or of an alloy; it is also easy to determine its electrical resistance. If the mass stands these tests well, its suitability for certain purposes is assured: but a subtle method of investigation has been afforded by the results of a research entrusted to me by a committee of

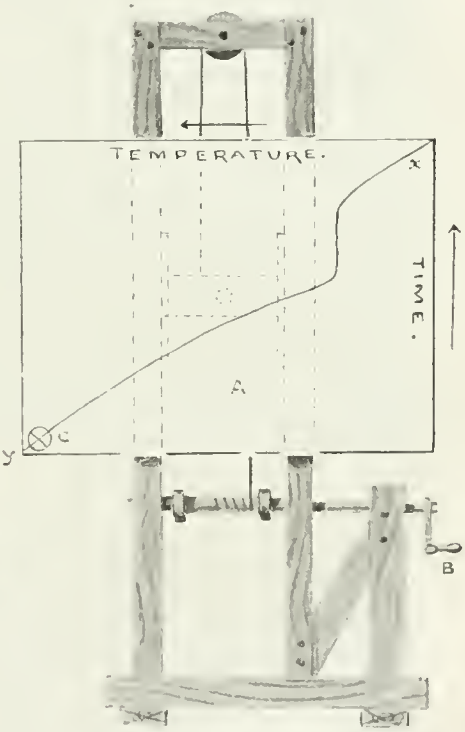

FIG. 3.

the Institution of Mechanical Engineers, over which Dr. Anderson, of Woolwich, presides. We can now gather much information as to the way in which a mass of metal has arranged itself during the cooling from a molten condition, which is the necessary step in fashioning it into a useful form; it is possible to gain insight into the way in which a molten mass of a metal or an alloy, molecularly settles itself down to its work, so to speak, and we can form conclusions as to its probable sphere of usefulness.

The method is a graphic one, such as this audience is familiar with, for Prof. Victor Horsley has shown in a masterly way that traces on smoked paper may form the record of the heart's action under the disturbing influence caused by the intrusion of a bullet into the human body. I hope to show you by similar records the effect, which though disturbing is often far from prejudicial, of the introduction of a small quantity of a foreign element into the "system" of a metal, and to justify a statement which I made earlier, as to the applicability of physiological methods of investigation to the study of metals. In order that the nature of this method may be clear, it

[1] *Ann. de Chim. et de Phys.* vol. iv. 1895, p. 305.
[2] *Comptes rendus*, vol. xxix. 1849, p. 48, 545, 712.
[3] The principal memoirs of M. Moissan will be found in the *Comptes rendus*, vol. cxv. 1892, p. 1031; *ibid.* vol. cxvi. 1893, pp. 347, 349, 549, 1222, 1225, 1429; *ibid.* vol. cxix. 1894, pp. 15, 20, 935; *ibid.* vol. cxx. 1895, p. 290. The more important of the metals he has isolated are uranium, chromium, manganese, zirconium, molybdenum, tungsten, vanadium, and titanium. There is an important paper by him on the various forms of the electric furnace in the *Ann. de Chim. et de Phys.* vol. iv. 1895, p. 365

it is considered that if a thermometer or a pyrometer, as the case may be, is plunged into a mass of water or of molten metal, the temperature will fall continuously until the water or the metal begins to become solid: the temperature will then remain constant until the whole mass is solid, when the downward course of the temperature is resumed. This little thermo-junction is plunged into a mass of gold; an electric current is, in popular language, generated, and the strength of the current is proportional to the temperature to which the thermo-junction is raised; so that the spot of light from a galvanometer to which the thermo-junction is attached enables us to measure the temperature, or, by the aid of photography, to record any thermal changes that may occur in a heated mass of metal or alloy.

It is only necessary for our purpose to use a portion of the long scale, and to make that portion of the scale movable. Let me try to trace before you the curve of the freezing of pure gold. It will be necessary to mark the position occupied by the movable spot of light at regular intervals of time during which the gold is near 1045°, that is, while the metal is becoming solid. Every time a metronome beats a second, the white screen A (Fig. 3), a sheet of paper will be raised a definite number of inches by the gearing and handle, B, and the position successively occupied by the spot of light, C, will be marked by hand.

You see that the time-temperature curve, x, x', so traced is not continuous. The freezing point of the metal is very clearly marked by the horizontal portion. If the gold is very pure the angles are sharp, if it is impure they are rounded. If the metal had fallen below its freezing point without actually becoming solid, that is, if superfusion or surfusion had occurred, then there would be, as is often the case, a dip where the freezing begins, and then the temperature curve rises suddenly.

If the metal is alloyed with large quantities of other metals, then there may be several of these freezing points, as successive groups of alloys fall out of solution. The rough diagrammatic method is not sufficiently delicate to enable me to trace the subordinate points, but they are of vital importance to the strength of the metal or alloy, and photography enables us to detect them readily.

Take the case of the tin-copper series: you will see that as a mass of tin-copper alloy cools, there are at least two distinct freezing points. At the upper one the main mass of the fluid alloy became solid; at the lower, some definite group of tin and copper atoms fall out, the position of the lower point depending upon the composition of the mass.

(To be continued.)

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE ordinary spring meeting of the Institution of Mechanical Engineers was held on Wednesday and Friday evening of last week, April 24 and 26, the President, Prof. Alexander B. W. Kennedy, F.R.S., occupying the chair both evenings. The following was down on the agenda of the meeting: Adjourned discussion on Captain H. Riall Sankey's paper on "Governing of Steam Engines by Throttling and by Variable Expansion"; the "Third Report to the Alloys Research Committee," by Prof. W. C. Roberts-Austen, C.B., F.R.S.; "Appendix on the Elimination of Impurities during the Process of making 'Best Selected' Copper," by Mr. Allan Gibb; "Appendix on the Pyrometric Examination of the Alloys of Copper and Tin," by Mr. Alfred Stansfield.

In the discussion on Captain Sankey's paper a number of members spoke. As a general result it may be stated that the position taken by the author in his paper was supported, viz.: that for certain purposes, governing by means of the throttle valve was to be preferred; whilst under other conditions variable expansion governors would have advantages over the other method. Captain Sankey in his contribution impartially discussed both systems, and his paper may be taken as a good model of what a memoir of the kind should be, no undue bias being shown on either side.

The report of Prof. Roberts-Austen was perhaps of even greater interest than those which have preceded it; whilst the two appendices of Messrs. Gibb and Stansfield discussed important practical details. A request had been made that the investigations of Warburg and Tegetmeier on molecular porosity, and their observations on the "Electrolysis of Glass"[1] should be repeated. It will be remembered that atoms of sodium were made to pass through glass at a temperature of 200° C. under the influence of the electric current. Lithium atoms were then made to follow along the tracks or molecular galleries left by the sodium, the lithium having a lower atomic volume and weight than the sodium. When potassium, having a higher atomic weight and volume, was substituted, it was not found possible to trace out the sodium. We are thus, the author said, confronted with a molecular porosity which can in a sense be gauged, and the mechanical influence of the volume of the atom is thus made evident. It will also be evident that there is a direct connection between the properties of a mass and the volume of its atoms. The results previously obtained were entirely confirmed and somewhat extended in the experiments the author had undertaken. The septa, or dividing partitions, in these fresh experiments, were made mostly of soda glass, of which thick bulbs were blown from barometer tube. In most of the experiments the glass was electrolysed, using mercury and an amalgam of some metal as cathode and anode respectively. The temperature was from 250 to 350° C. The electromotive force employed was 100 volts, and the current in the case of the sodium experiments averaged about one-thousandth of an ampere, and was sometimes as high as one-fiftieth of an ampere. When the glass bulbs were employed they soon became cracked, and the free passage of the current fused the glass, forming a well-rounded hole. In each experiment a safety fuse was placed in series, to stop the current in case of breakage. In experiments in which sodium amalgam had been placed in the bulb and pure mercury outside, sodium passed into the mercury to the extent of 0·03 gramme or 0·46 grain. In one experiment, which lasted eighteen hours, the amount of sodium found in the mercury was 0·0131 gramme, or 0·2022 grain. The quantity of electricity which passed through the glass was measured by the aid of an electrolytic cell placed in series, in which copper was deposited to the amount of 0·0206 gramme, or 0·3179 grain. Calculating the number of coulombs of electricity passed by means of the electrolysis of glass, the number 55 is found, and by the electrolysis of copper sulphate, 62; thus showing, as well as a rough approximate experiment could, that the passage of sodium into the mercury follows the ordinary law of electrolysis. It is doubtful whether the sodium from the amalgam actually penetrated right through the glass: but there can be no question that it replaced a considerable proportion of the sodium which the glass contained. An attempt to pass potassium through the same glass failed. Gold was then used, both in the form of amalgam and dissolved in metallic lead, but in the latter case the temperature employed was, of course, higher. No gold was found to have been transmitted through the glass; but the glass employed became coloured by gold, and minute spangles of the metal were found embedded in it. The same result was obtained when copper was used as an amalgam; and in this case minute nodules of copper were deposited below the surface of the glass, an effect which is highly suggestive in connection with the formation of mineral veins by earth currents. Sodium amalgam placed in a bulb and surrounded with mercury, but with no current, gave negative results, showing that simple diffusion did not play any important part in the results obtained. The fact that a current passes at all through glass is a proof that electrolytic action has taken place; so that, even if a metal be not actually transmitted through glass, the passage of a current indicates that sodium, potassium, or other metallic constituent of the glass, must be leaving it, and is probably replaced by one or more of the metals in the metallic bath which constitutes the anode.

The author next referred to an addition made to the recording pyrometer by means of which increased sensitiveness was obtained. The galvanometer, which affords the means of measuring the temperatures of the masses of metal or alloy under examination, may occupy one of two positions; it may either be nearer to the slit through which the ray of light falls upon the photographic plate, or it may be further away from it. It will be evident that two galvanometers may be used simultaneously, with the light from their respective mirrors playing

[1] E. Warburg, "Ueber die Elektrolyse des festen Glases," *Wiedemann's Annalen*, vol. xxi. 1884, p. 622. E. Warburg and F. Tegetmeier, "Ueber die elektrolytische Leitung des Bergkrystalls," *Wiedemann's Annalen*, vol. xxxv., 1888, page 455. F. Warburg, "Ueber eine Methode Natrium Metall in geschlossene Röhren einzuführen," *Wiedemann's Annalen*, vol. xl. 1890, page 1.

through the same slit upon the photographic plate. The further galvanometer can have a much lower resistance, and consequently greater delicacy, than the nearer one, so that, while the line photographed on the moving sensitised plate from the nearer galvanometer might represent a range of temperature of, say, 1500 degrees, the line traced by the mirror of the further galvanometer should represent only one-tenth of this. The angular deflection of the nearer mirror would not exceed the limits of the sensitised plate, while the mirror of the delicate galvanometer might traverse a far larger range. Both galvanometers would be connected "in parallel" with the same thermo-junction; and obviously any portion of the extended range which it was desirable to reflect on the sensitised plate could easily be caught by a suitable adjustment of the mirror on the further galvanometer. If, therefore, the thermo-junction is plunged into a mass of metal cooling from say an initial temperature of 1500 degrees, the whole of the cooling curve could be traced by the mirror of the less delicate galvanometer, while only the portion greatly magnified would be recorded by the mirror of the more delicate galvanometer. The first curve derived from the less delicate galvanometer would serve as a "calibration curve" for that afforded by the other galvanometer.

By means of diagrams exhibited on the walls of the theatre, a large number of cooling curves for electro-iron were shown, care being taken that the iron was exceedingly pure. The points of recalescence were well shown on these curves, which may be studied with interest in the *Transactions* of the Institution, as bearing on the question of allotropy of iron, which has already been fully discussed in a former report. The cooling-curve of an aluminium-copper alloy was also given. This was the alloy containing 6 per cent. of copper, used by Mr. Yarrow in the construction of torpedo boats for the French Government. Two freezing points were shown, one due to the main mass, and the other at a lower point due to the copper associated with the aluminium. The pyrometric examination of iron-aluminium alloys was also treated at some length, but it would be difficult to give results without reproducing the curves and the diagram shown.

One feature that may be noticed, however, was that the freezing point of iron alloyed with, say, one per cent. of aluminium, is but little lower than that of iron itself; that is to say, the melting point of nearly pure iron is only slightly lowered by a small addition of aluminium. Osmond had already shown that aluminium does not produce any considerable lowering of the freezing point of cast-iron; and the usually accepted idea that cast-iron or steel containing aluminium is very fusible, must be due to the fluidity of the metal when it is melted.

Another interesting point was that the samples of alloys used in these experiments were kept for some months before being analysed, and it was found that during this time those which contained from 40 to 60 per cent. of aluminium had spontaneously disintegrated, and had fallen to powder. The powder was not oxidised, but consisted of clean metallic grains, probably resulting from chemical changes which had gradually taken place in the solid alloy. Whether the iron and aluminium were in a state of solution or were chemically combined when molten, there can be little doubt that they are so combined in the metallic powder, as attempts to re-melt this powder have proved unsuccessful, which points to the formation of an infusible compound.

Some experiments made by Mr. Thomas Wrightson to ascertain whether the welding of iron is attended with a fall of temperature, as is the case in the regelation of ice, were next described. The welding was done by means of electricity and observations were taken by means of the pyrometer formerly described. The results have been communicated to the Royal Society, and tend to show that the welding of iron and the regelation of ice are analogous phenomena, a point of no small theoretical importance.

In his last report the author had called attention to the fact that M. André Le Chatélier had suggested that the prejudicial action of an element is due to its forming a fusible compound with the metallic mass in which it is hidden; while, on the other hand, the presence of an element which forms an infusible compound with the mass, promotes the formation of a fine grain and imparts strength. The author did not wish it to be supposed, however, that the action of the added element is due solely to its infusibility, or to its power of forming a fusible compound with a portion of the mass which contains it; for cases are numerous in which such an explanation does not apply. In this connection a suggestion made long ago by Raoult Pictet (*Comptes rendus*, vol. lxxxviii. 1879, pp. 855 and 1315), well deserved consideration. He urged that there must be a connection between the melting-points of metals and the periodic law of Mendeléeff; for he showed that for all metals there is a simple relation between their atomic weight, the amplitude of the movement of their molecules under the influence of heat, and their melting-point. Pure metals with high melting-points—such as platinum, iron, copper, and gold—are comparatively strong; and, conversely, metals with low melting-points—zinc, lead, cadmium, bismuth, and tin—are relatively weak. Metals with high melting-points must necessarily be coherent and tenacious, because much heat is required to drive their molecules apart in reducing them to the liquid mobile state in which the molecules have very small coherence; and therefore at ordinary temperatures much force must be applied to overcome the cohesion of the molecules and break the mass. Conversely, in metals with low melting-points a small elevation of temperature will overcome the molecular cohesion, and render them liquid—that is, will melt them. Such metals will be weak, the author continued, because if little heat is required to melt the metal, less force will be needed to tear it apart. Hence melting-point and tenacity are clearly connected. The absolute temperature of the melting-point of a metal must be closely connected with its atomic volume, because the former is inversely proportional to the rate at which the amplitude of the oscillations of the molecules increases with temperature; and the rate of increase of amplitude at any given temperature is obtained by multiplying the ordinary thermal coefficient of linear expansion by the cube root of the atomic volume.

Prof. Roberts-Austen here pointed out that the recent work of Dewar and Fleming (*Philosophical Magazine*, vol. xxxiv. 1892, p. 326) bears directly on this question. They employed very low temperatures, and show that at the absolute zero of temperature pure metals would probably offer no resistance to the passage of an electric current, but that the electrical resistance of alloys does not diminish so rapidly with the lowering of temperature as in the case of pure metals. Prof. Dewar (*Proceedings* of the Royal Institution, vol. xiv. part 2, 1895, p. 1) has shown, moreover, that the tenacity of pure metals and alloys is greatly increased by extreme cold—that is, by the closer approximation of their molecules; and this affords additional evidence that metals become stronger at temperatures which are further and further removed from their melting-points.

The discussion on this paper was of a somewhat brief nature, the reading of the report and the appendices, together with the carrying out of certain experiments and illustrations, taking a considerable time. Mr. Wrightson also explained at some length his welding experiments, which, as stated, have been placed before the Royal Society.

Prof. Goodman, of Leeds, gave some interesting particulars of the work upon which he has been engaged during the last two years in connection with anti-friction alloys. He had discovered that these substances must always contain a metal of high atomic volume, and there seemed to be a direct connection between the efficiency of the anti-friction of alloy and the atomic volume of one of its constituents. If the atomic volume of the alloy were small, then the friction was enormously increased, but with high atomic volume it was reduced. He had produced an anti-friction metal which would withstand a pressure of two tons to the square inch when running at 550 revolutions per minute, the temperature being 140°; that was a very remarkable result for a white metal. The alloy used had a higher atomic volume than bismuth, but he was not at liberty then to state the nature of the substance. He wished, however, to impress the necessity of absolute purity, or that if there were any impurities, they should be of high atomic volume.

Mr. Blount, in referring to the author's remarks on the electrolysis of glass, and the fact that potassium would not follow sodium and lithium, said he would be glad of an explanation why gold, which had a lower atomic volume than sodium, should not have traversed the "galleries" left in the glass by the sodium.

The summer meeting of the Institution will be held in Glasgow, commencing Tuesday, July 30.

THE ROYAL COMMISSION ON TUBERCULOSIS.

IN July 1890, a Royal Commission was appointed to inquire and report "what is the effect, if any, of food derived from tuberculous animals on human health, and if prejudicial, what are the circumstances and conditions with regard to the tuber-

culosis in the animal which produces that effect upon man. Lord Basing was the chairman, and the other commissioners were: Prof. G. T. Brown, Sir George Buchanan, Dr. G. F. Payne, and Prof. Burdon Sanderson. After the death of Lord Basing, in October last, the commission was reorganised with Sir George Buchanan as chairman. The report of this commission, upon the evidence and experimental inquiries received since the appointment of the original commission five years ago, was presented to Parliament last week. The general results of the inquiries instituted by the commissions in connection with the matter referred to them, will be found in the subjoined summary appended to the report:

"We have obtained ample evidence that food derived from tuberculous animals can produce tuberculosis in healthy animals. The proportion of animals contracting tuberculosis after experimental use of such food is different in one and another class of animals: both carnivora and herbivora are susceptible, and the proportion is high in pigs. In the absence of direct experiments on human subjects we infer that man also can acquire tuberculosis by feeding upon materials derived from tuberculous food animals. The actual amount of tuberculous disease among certain classes of food animals is so large as to afford to man frequent occasions for contracting tuberculous disease through his food. As to the proportion of tuberculosis acquired by man through his food or through other means we can form no definite opinion, but we think it probable that an appreciable part of the tuberculosis that affects man is obtained through his food. The circumstances and conditions with regard to the tuberculosis in the food animal which lead to the production of tuberculosis in man are, ultimately, the presence of active tuberculous matter in the food taken from the animal and consumed by the man in a raw or insufficiently cooked state. Tuberculous disease is observed most frequently in cattle and in swine. It is found far more frequently in cattle (full grown) than in calves, and with much greater frequency in cows kept in town cowhouses than in cattle bred for the express purpose of slaughter. Tuberculous matter is but seldom found in the meat substance of the carcase; it is principally found in the organs, membranes, and glands. There is reason to believe that tuberculous matter, when present in meat sold to the public, is more commonly due to the contamination of the surface of the meat with material derived from other diseased parts than to disease of the meat itself. The same matter is found in the milk of cows when the udder has become invaded by tuberculous disease, and seldom or never when the udder is not diseased. Tuberculous matter in milk is exceptionally active in its operation upon animals fed either with the milk or with dairy produce derived from it. No doubt the largest part of the tuberculosis which man obtains through his food is by means of milk containing tuberculous matter. The recognition of tuberculous disease during the life of an animal is not wholly unattended with difficulty. Happily, however, it can in most cases be detected with certainty in the udders of milch cows. Provided every part that is the seat of tuberculous matter be avoided and destroyed, and provided care be taken to save from contamination by such matter the actual meat substance of a tuberculous animal, a great deal of meat from animals affected by tuberculosis may be eaten without risk to the consumer. Ordinary processes of cooking applied to meat which has got contaminated on its surface are probably sufficient to destroy the harmful quality. They would not avail to render wholesome any piece of meat that contained tuberculous matter in its deeper parts. In regard to milk, we are aware of the preference by English people for drinking cows' milk raw—a practice attended by danger on account of possible contamination by pathogenic organisms. The boiling of milk, even for a moment, would probably be sufficient to remove the very dangerous quality of tuberculous milk. We note that your Majesty's gracious commands do not extend to inquiry or report on administrative procedures available for reducing the amount of tuberculous material in the food supplied by animals to man, and we have regarded such questions as being beyond our province."

THE GEOLOGICAL DEVELOPMENT OF AUSTRALIA.

BY the kindness of the Secretary of the Australasian Association for the Advancement of Science, we have been favoured with a complete account of the proceedings of the late meeting at Brisbane. The Hon. A. C. Gregory, C.M.G., the president of the meeting, took as the subject of his address "The Geographical History of the Australian Continent during its successive Phases of Geological Development." The subject afforded Mr. Gregory an opportunity for putting on record the knowledge he has gained from personal inspection of a larger proportion of Australian territory than has been explored by any other investigator. We are glad to be able to give the text of his address.

Primary Condition and Form of Land.

In dealing with the geological history of Australia, it is convenient to refer to the groups of formation, as the scope of this address is insufficient for the separate consideration of the component members of each group which has taken prominent part in the geographical establishment of sea and land. Like all histories of remote events, the evidence of what was the primary condition and form of the land is necessarily of very limited character, but some evidence does remain for our guidance. The earliest indications of the existence of land within the limits of the present Australian continent consists in the fact that many of the more elevated summits are composed of "granite," which is certainly the oldest rock formation with which we are acquainted.

It is here necessary to state that the term granite is used to indicate ancient or continental granite, and that the granitoid rocks, which are so closely allied in lithological aspect as to pass under the same designation, but are really intrusive masses of more recent date, even as late as the Permo-carboniferous period will be termed intrusive granite. Now the higher portions of the granite ranges show no superincumbent strata, while sedimentary beds fold round their flanks in a manner which indicates that the edges of these strata were formed near the margin of an ancient sea, above which the more elevated masses of granite rose as islands. As an instance of this early existence of land, we find on the present east coast that the granite tract of New England is flanked by Devonian slates and marine beds of spirifer limestones in positions which indicate that their deposition was in an ocean of at least 2000 feet in depth, above which the granite mountains rose to an elevation of 2000 feet. Adopting similar evidence as a basis for the estimation of the area of land at this earlier date, it appears that there existed a chain of islands extending from Tasmania northerly along the line of the present great dividing range, between the eastern and western streams nearly to Cape York, a distance of about 2000 miles, and with a breadth seldom exceeding 100 miles. In Western Australia a much broader area of dry land existed in the form of a granite tableland, the western limit of which, commencing at Cape Leeuwin, extended north for 600 miles, with a straight coast-line rising 500 feet to 1000 feet above the ocean. This land had a breadth east and west of about 200 miles, but its eastern shores were comparatively low and irregular, with probably detached insular portions, more especially on the northern side, as the stratified rocks in which the West Australian gold mines are worked have an exceedingly irregular outline where they overlay the granite. Between these eastern islands and the western land, there probably existed some granite peaks which rose above the ocean, but the evidence is that they were not of important area, and principally located in the northern parts. The remainder of the present continent was covered by an ocean gradually increasing in depth from the western land to the central part, and great depth continued to the shores of the eastern islands.

Sedimentary Deposits.

The next step in our history is that the natural decomposition of the granite, both terrestrial and marine, supplied material for sedimentary deposits; and we find a series of imperfectly stratified grit rocks, together with schists and slates, the former the results of the deposition of the coarser drifts, and the latter the more gradual deposit of the finer particles. These rocks, which are classed as Laurentian, Cambrian, and Silurian, did not extend far from the eastern islands, and are principally developed in Queensland to the north and in Victoria to the south, but, being of marine formation, they did not then materially affect the geographical configuration, though they are important features of the present time, and are the chief sources of our tin mines; and silver, lead, and copper also exist in sufficient quantity to afford prospect of future industrial success. There is also a marked characteristic in the abundant occurrence of fluor spar, which is an exceedingly rare mineral in the later formations.

while gold does not occur in important quantity except in its upper or Silurian strata in Victoria. Near Zilmantown (lat. 17° 20′ S., long. 144° 30′ E.) there are interesting developments of these rocks, which now form steep ranges with flat-bottomed valleys, in which coralline limestone of the Devonian period rests unconformably, and in places rises abruptly several hundred feet, presenting the form of ancient coral reefs, such as now exist on the great Barrier Reefs. In fact, they indicate that at some remote time a passage existed from the east coast to the southern part of the Gulf of Carpentaria, under similar conditions to those of the present Torres Straits, and that the subsequent elevation of the land has now placed it more than 500 feet above sea-level. This description of the present state of these rocks is, however, a digression in regard to geological sequences of the early period.

More Favourable Conditions.

The Cambrian and Silurian period was succeeded by the Devonian, during which there is little evidence of any great variation in the limits of the sea and land, but organic remains show that the conditions were becoming more favourable for the development of marine life. The rocks consist principally of fine-grained slates, which must have been deposited in a deep sea, and in some places the now visible sections indicate a thickness of 10,000 feet.

The upper strata connected with the Devonian series have been classed by geologists as belonging to the Permo-carboniferous, on account of the marine fossils which have been found in the Gympie series of rocks. Some difficulties, however, arise in regard to the identification of Australian rocks with those of Europe on the sole basis of the occurrence of nearly the same species of mollusca, and it may be remarked that in Central North America the appearance of fossil mollusca and plants, which would in Europe indicate a definite horizon, often occurs in rocks which lithologically and stratigraphically are of an earlier date; and the same conditions of the earlier appearance of species and genera seem to obtain in Australia, and if ultimately established would clear away many of the existing difficulties in the comparison of Australian and American fossils with those of Europe. Accepting the classification of the Gympie rocks as Permo-carboniferous, there was no important alteration in the geographical limits during the Devonian period, or in the earlier Permo-carboniferous Gympie beds, but shortly after this there were very decided variations in both the area and altitude of the land. The whole of the present continental area was raised sufficiently to lift large portions of the previous sea-bottom above its surface. The principal elevation was on the eastern coast, where the rise must have been several thousand feet; while on the west it was less pronounced, though the area added to the land appears to have included nearly the whole of what is now Western Australia. And in regard to the intervening space between it and the eastern ranges there is only the negative evidence, of no later marine deposits to indicate that it also was above the ocean. Although the general elevation of the continent appears to have been quiescent in the western and central parts, there were violent disruptions on the eastern coast, and the strata were apparently crushed by a force from the east which lifted them into a series of waves showing the faces of dislocation to the east and strata sloping to the west, the most easterly wave being near the present coast-line, and the succeeding waves more gradual as they recede to the west, both in angle and height, until they merge into the level of Central Australia. It is also probable that the South Australian range was also the result of this compression, causing the strata to rise in abrupt masses on an axis nearly north and south. It was at this stage of disruption and elevation of strata that the more important auriferous deposits of both the eastern and western parts of the continent were formed, and these may be divided into two classes—true fissure veins, or lodes, in which the deposits of ore are found filling fissures in the slate strata, and generally nearly vertical; and floors of ore which occur in sheets dipping at a less angle from the horizontal than the vertical, the including rock being of crystalline character, being, in fact, intrusive granites. The dip of these sheets of ore is in the direction of the huge dykes of intrusive rock in which they occur.

Auriferous Deposits in Lodes.

There was not only great disruption of the strata, but igneous rocks forced themselves into the fissures in the sedimentary beds, and the resulting metamorphism of the adjacent rocks increased the confusion, as beds of slate may be traced through the transformation of their sedimentary character, by the recrystallisation of their component elements into diorites having that peculiar structure of radiating crystals which usually characterise rocks of volcanic origin. As regards the auriferous deposits in these lodes, it appears that first simple fissures were filled with water from the ocean or deep-seated sources; but in either case the powerful electric currents which continually traverse the earth's surface east and west met resistance at the lines of disruption, and electric action being developed, the mineral and metallic salts in the water in the fissure and the adjacent rocks would be decomposed, and the constituents deposited as elements, such as gold and silver, or as compounds, such as quartz, calcspar, and sulphide of iron, all which were in course of deposit at the same time as the angles of the crystals cut into each other. There have been many speculations as to the source from which the gold was derived, but that which best accords with the actual conditions is that the metal exists in very minute quantities in the mass of the adjacent rocks, from which it has been transferred through the agency of electric currents and the solvent action of alkaline chlorides, which dissolve small quantities of the precious metals, and would be subject to decomposition at the places where fissures caused greater resistance to the electric current. One remarkable circumstance is that the character of the rocks forming the sides of the fissures has an evident influence on the richness of the ores in metals where lime, magnesia, or other alkaline compounds, or graphite, enter into their composition; the gold especially is more abundant than where the rocks contain silica and alumina only.

Queensland's Testimony.

In Queensland, Gympie affords some instructive examples of fissure lodes. In some, large masses of rock have fallen into the fissure before the ore was deposited, and have formed what miners term "horses," where the lode splits into two thin sheets to again unite below the fallen mass. The Mount Morgan mine may also be cited as a case where several fissure lodes rise to the surface in close proximity. The ore was originally an auriferous pyrites, but the sulphide of iron was largely decomposed, leaving the gold disseminated through the oxide of iron. In other cases the sulphur and iron have both been dissolved out, and left cellular quartz, with gold in the cavities or as fragments of gold, mixed with minute crystals of quartz, presenting the aspect of kaolin, for which it has been mistaken. The auriferous deposits, which occur in the intrusive granites, appear under conditions differing from the true lodes in sedimentary rocks, as the intrusive granitoid rock forms dykes which fill fissures in the older true granites, and also cut through the sedimentary slates. It bears evidence of intrusion in a state of fusion, or, at least, in plastic condition and subsequently crystallised, after which there has been shrinkage, causing cavities as the sides of the dyke were held in position by the enclosing rock. The vertical shrinkage being greater than the horizontal, the cavities were nearer the horizontal than the vertical, and being afterwards filled with ore, formed what are called "floors," one characteristic of which is the tendency to lenticular form, or a central maximum thickness with thinner edges. The Charters Towers goldfield exhibits a good illustration of this class of auriferous intrusive granite. Here the intrusive granite appears as a dyke of great thickness, exceeding a mile, with a length of twenty miles; the rock is well-crystallised quartz and felspar, with very little mica or hornblende. One shaft has been sunk 2000 feet to a floor showing gold, and similar to the floors that outcrop on the surface. The dip of these floors is north, about 30 degrees from the horizontal, and the strike across the direction of the dyke. There are, however, no good natural cross-sections, as the watercourses are small, so that the length and breadth have to be estimated to some extent by the character of the soil derived from the decomposed rock, it being more fertile than that of the other rocks in the locality. The exploratory shafts which have been sunk are in positions selected for the purpose of reaching known sheets of ore at greater depth, or under the impression that the ore deposits were true fissure lodes, and would have extension in the direction of the discovered outcrops, and therefore not calculated to extend our knowledge of the auriferous deposits. The most instructive instance of the occurrence of auriferous intrusive granite exists in the valley of the Brisbane River, near Eskdale, where a granitoid dyke, fifty yards wide, cuts through a slate hill for a distance of three miles, and in places shows thin sheets of quartz containing gold; the strike is at right angles to the length of the dyke, and the dip is 30 degrees. Some of the

quartz sheets have been traced across the dyke to within an inch of the slate which encloses it, but there is no trace of any variation in the sedimentary slate opposite the end of the quartz. A small watercourse cuts through the dyke and exposes arsenical pyrites and iron oxide, with small particles of gold. A more accessible instance of intrusive granite is exposed in the cutting for the bywash of the Brisbane Waterworks, at Enoggera, where the igneous rock has intruded between the strata of the slate.

Permo-carboniferous Rocks.

From the middle to the close of the Permo-carboniferous period the dry land teemed with vegetation, of which the Lepidodendron was a conspicuous type, along the eastern division, for though this plant was most abundant in Queensland, it is also found in Victoria, and on the Philips River, in West Australia, where the later Permo-carboniferous rocks are found on the south coast, extending from Albany eastward to Israelite Bay, forming the Stirling Range, with an elevation of 3000 feet, the Mounts Barren, and Russell Range. The age of these rocks is determined by the occurrence of large fragments of carbonised vegetation, the aspect of which closely resemble Lepidodendron stems. This formation is limited to the coast district, as, at a distance of fifty miles inland, the granitic plateau is reached with its partial colouring of Devonian slates. On the northern coast the Permo-carboniferous rocks are developed in the valley of the Victoria River for a hundred miles from the sea. Also on the Kimberley goldfield, to the south-west of Victoria.

Geographical Features.

The geographical features of this period appear to have been a continent somewhat similar in form to that of the present Australia. There was an elevated range along the east coast which attracted moisture, and a climate favourable to vegetation, and also by rapid degradation of its rocks supplied suitable soil for tropical growth. The central interior was not favoured by such a climate, and there are few traces of either deposit or denudation. The western interior enjoyed a moderate rainfall, and the detritus was carried down towards the north and south coasts, where it was deposited in regions where the carboniferous flora flourished, though not to the same degree as in East Australia, where it laid the foundation of the great coalfields of New South Wales and Queensland.

Further Elevation of Continent.

About the end of the Palæozoic or the commencement of the Mesozoic periods there appears to have been a further elevation of the continent, especially in the eastern part, for though in many places the deposits of the strata show little interruption, in others there has been considerable disturbance and unconformity of succession, with indications of an increase in the elevation of the land, which, with a contingent increase of rainfall, accounts for the luxuriant growth of the carbonaceous flora and its extension much further to the west. The artesian bores which have been made show that the cretaceous beds rest on the carbonaceous at a depth of 2000 feet below the present ocean level, and the fresh-water beds of the coal series are not less than 3000 feet in thickness, showing that the terrestrial level of the mountains has been decreased 5000 feet, or, in other words, they were 5000 feet higher during the Mesozoic period. On the western coast the elevation is not so well defined, but the land was at a greater height above the ocean than at present, as fragments of coal and its accompanying minerals have been washed up from the deep sea, and may be found embedded in the Tertiary limestones of the coast. There is thus proof that on the west coast the land extended further, and was covered with Australian fresh-water flora of the coal period; but this area is now submerged, and, taking into consideration the great depth of the ocean on this coast, the height of the land must have exceeded its present level by a thousand feet. Examining the ocean depths around the present Australian coast, even 5000 feet would make little difference in the limits of the west, south, and south-west coasts; but on the north and east the land would extend to the Great Barrier Reef. Papua would have been connected, and even the Arafura Sea and Island of Timor might have been brought within the limits of *Terra Australis*.

Elevation of Australia.

The mountain ranges of the east coast would be connected with those of Papua and form a magnificent series of summits of 13,000 feet elevation, a configuration that must have arrested the moisture from the Pacific Ocean, and resulted in a moist tropical climate, well calculated to support the luxuriant growth of the vegetation of the coal period so far as East Australia was affected, though it might also have had the effect of rendering the climate of Central and West Australia so dry as to render the land a desert during the continuance of this carbonaceous period. East Australia has thus, on its lower levels, accumulated stores of fuel for use in ages long subsequent. The luxuriant vegetation necessary to the production of coal was limited to the area east of the 140th meridian, except in a portion of South Australia, which seems to have been favoured by the overflow of some large rivers draining the western slopes of the Great Range, and had their outlet through Spencer's Gulf. The vegetation of Australia at this period, however well adapted for the formation of coal deposits, was not such as in the present would be suitable for the maintenance of mammalian life, as it consisted of ferns, cycadea, palms, and pine-trees, of which only the *Araucaria Bidwillii* has left a living representative, and its silicified wood from the coal formation presents exactly the same structure as the tree now growing on the ranges. Australian geography underwent little change during the Mesozoic period, but at the commencement of the Cretaceous a general subsidence of the whole continent began. The coal deposits ceased, and a fresh-water deposit known as the Rolling Downs formation accumulated, the constituents being soft shales, which in the earlier period supported a growth of ferns and pine timber. The land continued to subside until the ocean invaded a large portion of the lower lands, but only as a shallow sea, or possibly in the form of estuaries, as the fresh-water vegetation appears intercalated with marine limestones containing Ammonites and other mollusca of the Cretaceous epoch.

The Cretaceous Period.

The depression during the Cretaceous period must have been gradual and of long continuance. The ocean apparently first covered the land near the Great Australian Bight on the south, and Arnheim's Land on the north, as in each of these localities there are extensive deposits of thick bedded limestones, which may have continuity across the continent under cover of the ferruginous sandstones of the latter part of the epoch. On the east coast the ocean rose from 100 feet to 200 feet above its present level in Queensland, as the margin of the Cretaceous rocks is visible close to South Brisbane, and there is a belt along the coast from Point Danger to Gladstone. Further north there are extensive patches of Desert Sandstone belonging to this period, though the designation seems to have been applied to two distinct beds of sandstone, one belonging to the close of the Mesozoic, and the other to the last part of the Cretaceous.

Great Depression and Eruptions.

Ultimately the dry land was reduced to the eastern ranges, from Cape Howe northerly to lat. 15°; the eastern side nearly the same as the present coast line, and extending from 100 to 300 miles westerly, while the Mount Lofty Range in South Australia existed as an island. This great depression was accompanied by dislocations of strata and also the eruption of porphyritic masses, the age of these eruptions being easily determined as they rest on the Ipswich coal strata. At Mount Flinders the base of the mountain consists of coal shales with abundant impressions of *Pecopteris*, while there is a more instructive instance near Teviot Brook, where in a deep ravine there is a dyke of porphyry cutting through a bed of carbonaceous shale with *Pecopteris* and the silicified stems of pine-trees embedded. The dyke itself is dark-coloured and highly crystalline, but where it spreads out into a flat sheet on the top of the hill it assumes the same appearance as the light-coloured porphyry of Brisbane. This porphyry forms the Glass-house Mountains, which are so conspicuous from the entrance of Moreton Bay, and also Mounts Warning, Leslie, Maroon, and Barney.

The central and western parts of the continent were almost entirely submerged in the ocean, but not to any great depth, as the higher granite peaks of the north-west do not show traces of submergence, though the sedimentary deposits approach closely to their bases. The Stirling and Mount Barren Ranges on the south coast were only partially covered, as there is an ancient sea beach on the south side of middle Mount Barren, about 300 feet above the present sea-level. The interior tableland, though now of greater altitude than Mount Barren, was submerged, as evidenced by the extension over the whole of the rest of West Australia of soft sandstones and claystones in which salt and

gypsum are of common occurrence. On the northern coast the submergence was greater, as the sandstones and shales have a thickness of more than a thousand feet.

THE CRETACEOUS DEPOSITS.

One characteristic of the later part of the Cretaceous deposits is that in the lower part they consist chiefly of white, blue, and pale red shales, which readily disintegrate, while the upper portion consists of variegated sandstones of a harder character, with a comparatively thin covering of ferruginous concretionary pebbles or nodules, often with a nucleus of organic origin. On the west coast (latitude 29°), on Moresby's Flat-topped Range, these features are well developed, and in the upper part a bed of limestone, containing Ammonites and other mollusca of the Cretaceous series. And it was from this locality that the first proofs of the existence of the Cretaceous formation in Australia were furnished to Prof. M'Coy. Closely associated with these limestones are ferruginous sandstones, containing casts of large accumulations of fragments of wood and vegetable débris, such as may be found after floods on the margins of rivers, indicating an estuarine system, where fresh and salt water alternated.

AUSTRALIA AN ISLAND.

The Mesozoic period closed with Australia reduced to the area of a large island on the east coast and some small islands on the south-west and north-west of the present continent, and then the connection with Papua was severed

A NEW ELEVATION.

Early in the Tertiary period a new elevation of the land commenced, but the rise was not attended by any great disturbance of the strata, as in almost every instance where the Upper Cretaceous rocks remain they are remarkable for their horizontal position. The elevation of the continent on this occasion was nearly equal in all parts; the ultimate altitude was at least 500 feet greater than at present, and the geographical effect was that Australia assumed nearly its present limits.

FEATURES OF THE CONTINENT.

The features of the continent at this time appear as high ranges on the east coast and a nearly level tableland extending to the west coast, but the whole of the interior with a general incline towards Spencer's Gulf. Short watercourses flowed direct to the sea, but far the greater area was drained by much longer streams towards Spencer's Gulf, while a secondary series occupied the basin of the Murray and Darling Rivers. The climate evidently differed greatly from that now existent, as the denudations of the tableland removed tracts of country many hundreds of square miles, each forming immense valleys bounded by flat-topped hills and ranges representing the marginal remnants of the original surface. Enormous quantities of the finer-grained portions of the degraded shales must have been swept into the ocean by the rivers, but the coarser sands have been left in what is now the desert interior, where the wind drifts it into long steep ridges of bright red sand, having a northerly direction near the south coast, but spreading out like a fan to the east and west in the northern interior.

VALLEYS AND RIVER SYSTEMS.

The interior rivers formed a grand feature of the country so long as the rainfall continued sufficiently copious to maintain their flow, but in the arid climate which now obtains it does not even compensate for the evaporation. The river channels have been nearly obliterated, and some parts of the wider valleys changed to salt marshes or lakes, such as Lakes Amadeus and Torrens, while the entrance to Spencer's Gulf is choked with sand. It was during this period when the great valleys of the river systems were being excavated that a great proportion of the outbursts of volcanic rock in the form of basalt occurred. The age of these basalts is established by their superposition on cretaceous rocks. Thus, at Roma, the Grafton Range is a mass of basalt, resting on the cretaceous sandstones and shales. Mount Bindango is a similar instance. On the Upper Warrego there is a deep ravine through cretaceous rocks partly undermining a basaltic cone. On the Victoria River a large basin has been eroded in the cretaceous rocks and then several hundred square miles flooded by an eruption of basalt, through which watercourses have cut instructive sections, showing the subordinate sandstones baked and fused by contact and the cracks filled by the covering basalt.

It does not appear that the eruption of basalt has materially affected the geographical outline of the coast, but there were considerable variations of level and important tracts of fertile country formed by the basaltic detritus, such as Peak Downs and Darling Downs in Queensland, and to the west of Melbourne in the south.

LARGE ANIMAL PERIOD.

It was not till after the convulsions which attended this outflow of basalt, and lakes, marshes, and rivers had been formed, and produced a luxuriant growth of vegetation, that the gigantic marsupials gave any decisive evidence of their advent, as their fossil remains are found in the drifts of watercourses mixed with basaltic pebbles and detritus. The physical conditions of the country during the period of the Diprotodon, Nototherium, and associated fauna, differed materially from that which now subsists, for the structure of the larger quadrupeds would render them incapable of obtaining a subsistence from the short herbage now existing in the same localities, and it is evident that their food was of a large succulent growth, such as is found only in moist climates and marshy land or lake margins. This view is also supported by the fact that on the Darling Downs and Peak Downs the associated fossils include crocodile and turtle, so that what are now open grassy plains must have been lakes or swamps, into which the streams from the adjacent basaltic hills flowed, and, gradually filling the hollows with detritus, formed level plains.

ENORMOUS RAINFALLS.

That this gradual filling up of lakes actually occurred is shown by the beds of drift which are found in sinking wells and in sections exposed by erosion of watercourses; but in all these instances there is evidence that the ancient rainfall was excessive, as even our present wettest seasons are inadequate to the removal of the quantities of drift which have been the result of a single flood in the ancient period. On the ridges around the lakes there existed a forest growth, as many species of opossum have left their bones as evidence; but the timber evidently differed from the present scanty growth of eucalypti. Whether the same abundant rainfall extended far into the western interior is uncertain, but the rivers evidently maintained a luxuriant vegetation adapted to the sustenance of these gigantic animals, as the discovery of a nearly complete skeleton of Diprotodon on the shore of Lake Mulligan, in South Australia, shows that these animals lived in this locality, as it is not probable that their bodies could have floated down the Great River which drained the interior of the continent through Lake Eyre.

ANOTHER CHANGE.

It is evident that the climate gradually became drier, that the rivers nearly ceased their flow, and the lakes and marshes became dry land, while the vegetation was reduced to short grasses that no longer sufficed for the subsistence of the huge Diprotodon and gigantic kangaroo, though some of the smaller may still survive to keep company with the dingo, who, while he left the impressions of his teeth in the bones of the Diprotodon, has shown a greater facility for adapting himself to altered conditions. Is this the survival of the fittest? It was in these days that some of the rivers flowing direct to the coast cut through the sandstones into the softer shales beneath, and by their erosion formed considerable valleys bounded by rocky cliffs, and when the land was subsequently depressed the sea flowed in and formed inlets, of which Sydney Harbour and the entrance to the Hawkesbury River on the east coast, Port Darwin and Cambridge Gulf on the north-west, and the Pallinup River on the south-west of the continent may be cited as examples.

CONCLUSION.

Thus Australia, after its first appearance in the form of a group of small lands on the east, and a larger island on the west, was raised at the close of the Palæozoic period into a continent of at least double its present area, including Papua, and with a mountain range of great altitude. In the Mesozoic times, after a grand growth of vegetation which formed its coal beds, it was destined to be almost entirely submerged in the Cretaceous sea, but was again resuscitated in the Tertiary period with the geographical form it now presents. Thus its climate at the time of this last elevation maintained a magnificent system of rivers, which drained the interior into Spencer's Gulf, but the gradual decrease in rainfall has dried up these watercourses, and their channels have been nearly obliterated, and the country changed from one of great fertility to a comparatively desert interior which can only be partially reclaimed by the deep boring of artesian walls.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The preliminary resolutions in reference to the admission of graduates of other Universities to courses of advanced study and research were passed *nem. con.* by the Senate on April 25. The Syndicate for the purpose will now proceed to frame the detailed regulations for carrying the scheme into effect.

An Exhibition of fifty guineas a year for three years is offered by the Clothworkers' Company for the encouragement of Physical Science. Candidates must be non-collegiate students of one term's standing, or persons not yet in residence who propose to become non-collegiate students next October. The examination will be held next July. Information as to conditions, &c., may be obtained from the Censor, Fitzwilliam Hall, Cambridge.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, April 22.—M. Marey in the chair.—On the effects of the air carried below, without gyration, in the interior of tempests, water-spouts, and tornados, by M. H. Faye. The author shows that water-spouts are of the same type as, though on a smaller scale than, cyclones and typhoons. He illustrates by an experiment the character of the air-movements in the case of a water-spout. A gyratory movement at the base of a cloud causes the formation of a descending cone which has no effect below until the apex reaches the ground or water, when the air from above carried down in the centre of the cone escapes with violence in every direction. The phenomenon consists then of an interior comparatively calm core, down which proceeds air from the upper regions, and this is surrounded by a shell of cloud having a rapid rotatory motion. The analogy of the air-movements in cyclones and typhoons is brought out by a detailed consideration of (1) a storm encountered by the corvette *l'Eglé*. (2) a typhoon which passed centrally over Manilla Observatory on October 20, 1882. The calm column in the latter case was much hotter (11°) and drier than the surrounding shell of storm; the direction and force o the wind, temperature, and humidity were continuously registered, and completely bear out the explanation advanced.—On a new type of wells in the granitic rocks of Sweden, by M. Nordenskiold. These are artesian wells bored to a depth of from 30 to 50 metres in solid crystalline rocks in the hope of meeting with water coming through horizontal cracks expected to occur in the mass owing to the variations of temperature suffered by the surface portions. Such cracks supplying sweet water have invariably been encountered at a depth of 33 to 35 metres.—On a new deposit containing uranium, by M. Nordenskiold. A uraniferous substance giving nitrogen (see "Notes," p. 8).—Crystals forming at the bottom of a solution of greater specific gravity than themselves, by M. Lecoq de Boisbaudran. The inverse effect to that previously described by the author, where substances were shown to crystallise under some circumstances at the top of solutions of less specific gravity than the crystals. Crystals of sodium sulphate, floating on a solution of sodium iodide saturated with the sulphate, gradually disappeared, re-crystallising around a sulphate crystal previously fixed at the bottom of the solution. The same phenomenon occurs with ice in a dilute ammoniacal solution. This action depends on small temperature variations, as previously explained.—Every algebraical surface may be described by means of an articulated system, by M. G. Kœnigs.—On curves of the fourth class, by M. Georges Humbert.—On the dilatation of water, by M. Stephane de Lannoy. The author discusses the dilatometer method of taking the expansion of water, and tabulates his results with three instruments. A table is then given comparing the mean results with Rosetti's values, and with the corresponding quantities calculated from these values for the same temperatures by the air thermometer.—Specific heat and boiling point of carbon, by M. J. Violle. Above 1000° C. the mean specific heat of graphite increases linearly with the temperature, thus $C_0^t = 0.355 + 0.00006t$. 2050 calories are given up by 1 gram of graphite on cooling from the volatilisation temperature to 0°. The temperature of ebullition must therefore be 3600° C.—Electric resistance at the contact of two metals, by M. Edouard Branly. It is shown that certain pairs of metals, such as copper-zinc, have no contact resistance, whereas other pairs, lead-aluminium, lead-iron, tin-aluminium, tin-iron, bismuth-iron, bismuth-aluminium for instance, have an electric contact resistance.—On an optical method of analysing alternating currents, by M. J. Pionchon.—On photography in natural colours, by the indirect method, by MM. Auguste and Louis Lumière. Several negatives are prepared with differently coloured screens, and each is used to print off in a layer of the appropriately tinted bichromated-gelatine.—Molecular rotation and molecular deviation, by M. Ph. A. Guye.—On some derivatives of quinone-diorthoamido-benzoic acid, $C_6H_2O_2(NH.C_6H_4.CO_2H)_2$, by MM. J. Ville and Ch. Astre.—Remarks on the *pars intermedia* of Weisberg, by M. A. Cannieu.—On the absorbent power of the bladder in man, by MM. A. Pousson and C. Sigalas. Healthy vesical epithelium is impermeable in general, but absorption may take place (1) when the subject with a healthy bladder requires to void its contents, the urine then bathing the prostatic portion of the urethra; (2) when the vesical epithelium is altered.—On the seat of the colouration of brown oysters, by M. Joannes Chatin.—On the presence of a diastase in *vins cassés*, by M. G. Gouirand.

Erratum.—In the last report, p. 622, line 19 from bottom of second column, "left-handed" curves should read "skew" curves.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Anales del Museo de la Plata. Paleontologia Argentina, ii. and iii. (Contributions to a Knowledge of the Fossil Vertebrates of Argentina): R. Lydekker (La Plata).—A Manual of Forestry: Prof. W. Schlich. Vol. 3: Forest Management (Bradbury).—Organic Chemistry: Prof. I. S. Scarf (Collins).

THE PYGMIES.

The Pygmies. By A. de Quatrefages. Translated by Frederick Starr. (London and New York: Macmillan and Co., 1895.)

SOME surprise was expressed when Prof. de Quatrefages was appointed, in 1855, to the chair of Anthropology in the Museum of Natural History at Paris. He was then forty-five years of age, and had acquired a considerable reputation as a zoologist, but his published original researches related only to the lower marine forms of animal life. Thenceforward, however, he devoted himself with great energy and success to the cultivation of the subject under his special charge, and the great development of the collections in the Museum and the numerous contributions to the literature of the natural history of man, which he continued to make almost up to the time of his death, three years ago, at the age of eighty-two, abundantly justified his selection for the post. It is true, that during the greater part of this time he had the advantage of the assistance and harmonious co-operation in much of his work of M. E. T. Hamy, who has naturally succeeded to the chair.

The work now under notice, which has just appeared in an English form, was originally published in 1887, as one of the "Bibliothèque scientifique contemporaine," and is essentially popular in its character. It commences by giving an account of the wide-spread belief among the more cultivated nations of antiquity in the existence of a race or races of human beings of exceedingly diminutive stature, who dwelt in some of the more remote and unexplored regions of the earth. The scattered notices of these people, called *Pygmies* by the Greeks, found in the writings of Homer, Aristotle, Herodotus, Ctesias, Pliny, Pomponius Melo, and others, are cited and commented upon. Aristotle places his pygmies in Africa, near the sources of the Nile, and Herodotus gives a circumstantial account of their existence near a river now generally identified with the Niger, while Ctesias describes a race of dwarfs in the interior of India. Whether these legends were merely the offspring of a fertile imagination, or whether they had a solid foundation in fact, may be still an open question. Our author is convinced that the latter view is correct, and devotes the greater part of the work to the task of collecting all the reliable information upon the existing races of people of diminutive stature who inhabit the regions of the earth in which the pygmies of the ancients were supposed to dwell, and to the endeavour to harmonise the scanty notices of those old writers with the facts as now shown by scientific investigation.

A considerable portion of the book is given to an account of the characteristics and culture of that singularly interesting race, the natives of the Andaman Islands, which is naturally taken mainly from the observations of Mr. E. H. Man. These people Quatrefages persists in calling "Mincopies," although it has long been shown that the name is quite unknown in their own language. A chapter is then devoted to showing that people having the general physical characters (small stature, black colour, frizzly hair, and roundish heads) and many of the habits and customs (especially the dexterous use of the bow) of the Andamanese, form a groundwork of the native population of many of the islands of the Malay Archipelago, living mostly in the mountainous regions of the interior. To this race, Quatrefages has given the name of "Negrito." But it is not only in the islands that the Negrito race dwell. Traces of them are found also on the mainland of Asia, but everywhere under the same conditions; in scattered tribes, occupying the more inaccessible mountainous regions of countries otherwise mainly inhabited by other races, and generally in a condition more or less of degradation and barbarism, resulting from the oppressive treatment they have received from their invading conquerors; often, moreover, so much mixed that their original characters are scarcely recognisable. The Semangs of the interior of the Malay Peninsula, the Sakays from Perak, the Moys from Annam all show traces of Negrito blood. In India proper, especially among the lowest and least civilised tribes, not only of the central and southern districts, but almost to the foot of the Himalayas, in the Punjab, and even to the west side of the Indus, according to Quatrefages, frizzly hair, negro features, and small stature, are so common that a strong argument can be based on them for the belief in a Negrito race forming the foundation of the whole pre-Aryan or Dravidian, as it is generally called, population of the peninsula. The crossing which has taken place with other races has, doubtless, greatly altered the physical characters of this people, and the evidences of this alteration manifest themselves in many ways; sometimes the curliness of the hair is lost by the admixture with straight-haired races, while the black complexion and small stature remain; sometimes the stature is increased, but the colour, which seems to be one of the most persistent of characteristics, remains. The localities in which the Negrito people are found in their greatest purity, either in almost inaccessible islands, as were the Andamans till in comparatively recent times, or elsewhere in the mountainous ranges of the interior only, and their social conditions and traditions wherever they exist—all point to the fact that they were the earliest inhabitants; and that the Mongolian and the Malay races on the east, and the Aryans on the west, which are now so rapidly exterminating and replacing them, are later comers into the land. We now see what constitutes the great interest of the Andamanese natives to the student of the ethnological history of the Eastern world. Their long isolation has made them a remarkably homogeneous race, stamping them all with a common resemblance not seen in the mixed races generally met with in continental areas. They are the least modified representatives of the people who were, so far as we know, the primitive inhabitants of a large portion of the earth's surface, but who are now verging on extinction.

The next portion of the book is devoted to an examination of the so-called "pygmy" races of the African continent. These are the well-known Bushmen or "Sân" of South Africa, to whose religious beliefs a whole chapter, derived mainly from the observations of Hahn, is devoted, and another race to which Hamy has given the name of "Negrillos," about which far less is known at present, who seem to hold the same relation to the larger

long-headed African negroes, among whom they dwell, that the small round-headed Negritos of the Indian Ocean do to their larger long-headed Melanesian neighbours. Scattered communities of these small negroes, all much resembling one another in size, appearance and habits, scarcely over four feet in height, and all great hunters, expert with the bow, and living on the produce of the chase, occur at various isolated spots across the great African continent, within a few degrees north and south of the equator, extending from the Atlantic coast almost to the Indian Ocean. In many parts, especially at the west, they are obviously holding their own with difficulty, if not actually disappearing, and there is much about their condition of civilisation and the situations in which they are found, to induce us to look upon them, as in the case of the Bushmen to the south and the Negritos in the east, as the remains of a population which occupied the land before the incoming of the main body of the present natives. If the account of the Nasamonians, related by Herodotus, be accepted as historical, the river they came to, "flowing from west to east," must have been the Niger, and the northward range of the dwarfish people far more extensive twenty-three centuries ago than it is at the present time.

The translator has given, in an appendix, a list of the principal contributions to the literature of the little races of man which have appeared since the publication of the French edition of M. de Quatrefages' book. It would have been still better if he had given some epitome of the considerable advances that have been made in our knowledge of the subject, especially of the recent researches of R. G. Haliburton and Kollmann, which tend to show the former extension of dwarf races over a considerably larger area of the earth's surface than was suspected by our author, such as the whole of North Africa, the Pyrenees, Switzerland, and even Central America.

W. H. Flower.

AN ATTEMPT TO POPULARISE EVOLUTION

A Primer of Evolution. By Edward Clodd. (Longmans, Green, and Co., 1895.)

THE title of this little book is hardly justified by its contents, since it nowhere defines or explains evolution, or deals with it in a systematic manner. As the author tells us in a prefatory note, the book is an abridgment of his former work, "The Story of Creation"; and he does not appear to have made any attempt to rearrange his materials, or to introduce such new matter as was required to constitute it a real introduction to the theory of evolution for those who know little or nothing about it. Such a book should give, at starting, a full statement of what is meant by evolution in modern science and philosophy; should explain how it differs from previous theories of the universe; and should clearly mark out its range of action and its limitations, showing in what way it is supposed to have "evolved" the material universe, and how much must be postulated as the materials and the forces with which it works.

But instead of any explanation of this nature, the first half of the book is devoted to a general descriptive sketch of the universe, inorganic and organic, so brief and elementary as to be quite unnecessary, since any one prepared to enter on the study of evolution would be already acquainted with so much of the facts to be explained. In all this portion, occupying more than half the book, evolution is not once referred to. Then, in the second part, which is headed "Explanatory," all the ground is gone over again, with explanations which assume evolution, but do not often refer to it. Some of this is interesting and well written, the chapter on "Proofs of Derivation of Species" being one of the best; and if this part had been more fully developed, and had been preceded by such an account of the principle of evolution as has been suggested, the work might have been useful to beginners.

But, besides these deficiencies of arrangement and of subject matter, there are more serious defects in numerous obscurities and misstatements, and in the adoption of very doubtful theories as if they were universally accepted. As examples of these faults, the very first sentence states that—"The universe is made up of matter and motion," as if they were things of the same nature. And on turning to the "explanatory" part, we are informed that the "materials which make up the universe" are "matter and motion." On page 3, we are told that "matter is made up of chemical units or elements," about seventy in number, and that "These elements are named atoms." On page 91, we have force and energy defined as being respectively "motion which draws the atoms together," and "motion which drives the atoms apart." This appears to have been adopted from a well-known popular writer, but as it is quite different from what is to be found in the usual text-books it should not have been adopted in a "primer." At page 95, the friction of the ethereal medium in retarding the orbital motion of the planets, is stated as if it were a demonstrated fact. The abundance of the compounds of carbon are said to be partly due to its having "an affinity for itself" (p. 102); and among the erroneous statements of fact we are told that, among the lower races the great toe survives "as a grasping organ" (p. 127), and that there are in America certain wandering tribes who use gestures as "the sole mode of communication" (p. 157). Again, without a word of doubt or reservation, we have the statements that "The origin of life is not a more stupendous problem to solve than the origin of water" (p. 103); and that "mind is the highest product of the action of motion upon matter" (p. 174). These few samples are sufficient to show that this little work requires very careful revision to render it a safe guide for the elementary student.

STEEL AND THE NEW IRON-ALLOYS.

Steel Works Analysis. By J. O. Arnold. (London: Whittaker and Co., 1895.)

CHEMISTS engaged in steel works have long been wanting a trustworthy manual adapted to their special requirements, and this work is the latest attempt to meet the want. The work is undoubtedly an advance on its predecessors, for, while it retains the best of the well-known processes, many newer operations are now, for the first time, published in a comparatively handy form. Everything that a steel works analyst may fairly be called upon to examine, finds a place in this volume.

This applies more especially, perhaps, to the sections treating on the examination of chrome-iron, silicon-iron, nickel alloys, &c.

The volume is particularly valuable as embodying the results of an extensive experience in the examination of certain iron alloys which are bound to become of special importance in the near future; most steel works analysts will cordially appreciate this portion.

As the results of my own practice, I can confirm the accuracy and efficiency of most of the selected methods; more especially as applied to the assay of ferro-chrome, ferro-aluminium, silicon, nickel, &c.

In regard to the assay of ferro-chrome or steels, Galbraith's method is to be preferred, if the precautions given are adopted. The original process did not always give concordant results. The gravimetric methods are, however, on the whole most trustworthy. Results are apt to be low unless great care is taken; no doubt for the reasons shown at page 207. The estimation of small quantities of aluminium presents difficulties not easily overcome; indeed, simpler and less complicated methods are required: a remark which applies to most of the methods now practised.

The assay processes for sulphur and phosphorus are clearly set forth, leaving practically nothing to be desired. For the former element, certainly, gravimetric estimations are best; but it is nearly impossible to obtain the necessary acids quite free from sulphur compounds: this constitutes a serious drawback, and entails the necessity of a blank experiment, which should be avoided when possible. The evolution methods give only relative results, agreeing pretty closely amongst themselves, but somewhat under those obtained gravimetrically. The author's colour test is a good one, but somewhat complicated. A more simple modification of the colour test consists in passing the evolved H_2S through 50 c.c. of a very dilute lead acetate solution ($\frac{1}{10}$ grm. in litre H_2O) contained in a long test-tube. This is compared with a standard steel, treated in the same manner, containing a known percentage of sulphur. No precipitate is formed, and a clear brown tint is obtained, which lasts for some time, and is easily compared with the standard.

The processes advocated for phosphorus (pp. 110-115) are complete, but the necessary manipulative skill required to carry them out can only be acquired by constant practice. I find, however, that the addition of a little HCl to the nitric acid solution assists the precipitation of phosphorus when precipitating with ammonium molybdate. Further, I agree with the author that in ordinary steels the presence of silicic acid may be ignored: with regard to time, fifteen or twenty minutes is ample; if longer, molybdic acid is precipitated. In addition, even if this does not occur, the precipitate may redissolve to a notable extent. The dried phospho-molybdate precipitate is distinctly soluble in dilute nitric acid.

The author's method of precipitating arsenic with H_2S is good, but no others are given. The process with modifications gives good results, but the ordinary method is preferable when it is desired to estimate this element. For the mere elimination of arsenic from the phosphoric acid, in order to determine the latter, the boiling or distillation process is useful.

It is to be regretted that no trustworthy process has been given for the determination of oxygen in steel. A thorough examination of the whole work, however, reveals the pains taken by the author, not only as regards the portions mentioned in the foregoing, but also in the somewhat less important sections dealing with fuel and other materials. There can be little question that Prof. Arnold has rendered steel-works analysts a decided service by the publication of his work. JOHN PARRY.

OUR BOOK SHELF.

Wayside and Woodland Blossoms. A Pocket Guide to British Wild Flowers for the Country Rambler. By Edward Step. With coloured figures of 156 species, black and white plates of 22 species, and clear descriptions of 400 species. (London: Frederick Warne and Co., 1895.)

MANY persons who admire the beautiful flowers that adorn our woods and pastures would fain know their names, with a view to further knowledge of them; but for various reasons they are unable to use the ordinary "Flora," however simply compiled. Here is a little book that will meet the wants of such persons, and do more, we believe, to lay the foundation of a sound knowledge of plants than the form in which "life-histories" are taught in ordinary schools and classes for the purpose of passing an examination. In spite of all that is said to the contrary, to know a large number of plants, animals, or minerals by sight, is of more value, to begin with, than a more detailed knowledge of a single, or few, organisms or objects; especially when this detailed knowledge is gained by rote, and not by observation. We therefore commend this little book to the notice of those interested in, and believing in, small beginnings, though the kind of information it contains is not exactly what the examiner demands. The coloured figures are well drawn, and the colouring, although a little crude, is good enough to enable one to recognise the plants the figures are intended to represent. The majority of the common and prominent plants of our native flora are figured. Many of them are drawn of the natural size, whilst others are reduced and a few enlarged, without indications of the reduction or enlargement. These things should be explained for a beginner. The descriptive and explanatory letterpress is instructive, and free from pedantry, by which we mean the display of technical terms only used by "teachers" of botany; not by botanists. There are some inconsistencies in the choice of subjects for illustration. For example, the exceedingly rare *Holosteum umbellatum* is represented, whereas the allied genus *Cerastium*, found in every county, and perhaps in every parish and field in the kingdom, is left out. There is also an unexplainable absence of characteristic sea-side plants. The black and white figures mentioned in the title represent native trees and some of the commonly-planted exotic species. An omission here is the common yew, which might well have taken the place of the very poor figure of *Ailantus*. In spite of the shortcomings indicated, we strongly recommend this little pocket-book to those in search of some practical knowledge of common wild plants. W. B. H.

The Lepidoptera of the British Islands; a Descriptive Account of the Families, Genera, and Species indigenous to Great Britain and Ireland, their Preparatory States Habits, and Localities. By Charles G. Barrett, F.E.S. Vol. ii. Heterocera, Sphinges, Bombyces. (London: L. Reeve and Co., 1895.)

MR. BARRETT'S great work on British *Lepidoptera* is making steady progress, and we are glad to find that the second volume which includes the Sphinges and the first

nine families of Bombyces, ending with the *Psychidæ*, is written in the same careful and painstaking manner as its predecessor. The first volume has been well received abroad, but the foreign critics regret the absence of references, a deficiency more felt by them than by British lepidopterists. The foreign critics speak of the plates as a veritable storehouse of remarkable varieties; but we must again comment very severely on the action of the publishers in issuing two editions of the work, one with, and the other without illustrations, without any reference to the illustrated edition in the letterpress of the other, so far as we have noticed; and in the case of the second volume, without even as much as an advertisement to call attention to its existence.

There are several points of general scientific interest suggested by an examination of Mr. Barrett's book. A great number of species recorded as British by the older entomologists, but rejected by Doubleday and Stainton, have latterly been rediscovered and reinstated. This has happened so often, that it seems likely that when we eliminate accidentally introduced species (chiefly North American), and European species wrongly determined, it will be found that the information given by the older writers was far more accurate than the writers of the middle of the century were at all disposed to admit. Nor did the latter allow for the difficulty of communication with the continent at the beginning of the century, which added much to the improbability of specimens asserted to have been taken in England, having been simply brought over from the continent.

In estimating the probability of a reputed species being truly British, the chief factor to be taken into account is its continental range. It is evident that the British fauna is slowly changing, some specimens becoming rarer or even disappearing, and others becoming commoner, or establishing themselves in England for the first time. There is also some tendency in Mediterranean species to extend their range further north in Western Europe. As the late Mr. Stainton once remarked, the comparison of our present lists with those of the future, will be likely to yield highly unexpected and interesting results.

W. F. K.

Quellenkunde. Lehre von der Bildung und vom Vorkommen der Quellen und des Grundwassers. Von Hyppolyt J. Haas. 8vo. pp. 220. Illustrations in the text. (Leipzig: J. J. Weber, 1895.)

PROF. HAAS, of Kiel, when asked to edit and bring up to date the "Quellenkunde" of Abbé Paramelle, came to the conclusion that in order to state the present position of the science of springs and underground water in a satisfactory form, an entirely new work was necessary. Hence the book under notice. In such small compass, nothing approaching a complete treatise could possibly be attempted. The chief features of springs, their classification and relation to geological conditions, are discussed according to a clearly arranged plan under five principal heads. First comes a discussion of springs in general, including an historical introduction, in illustration of which several of Athanasius Kircher's quaint pictures are reproduced. The following sections deal with thermal and mineral springs, underground water, and the art of finding springs. In the last division we find some remarks on the divining rod. The book should prove useful to students of physical geography and to those concerned with the practical utilisation of a water-supply derived from wells.

A number of diagrams are reproduced from the works of Daubrée and other authorities. Although several English authors are cited, we fear that Prof. Haas has not made himself familiar at first hand with the literature of the subject in English, which is by no means meagre in records of original observations on the movements of underground water, and deserves more recognition than it receives.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Uniformitarianism in Geology.

DR. ALFRED WALLACE, in his letter to NATURE of May 2, calls attention to the significant fact that catastrophes caused by volcanoes "may be of greater magnitude now than in geologic times," owing to the crust of the earth being thicker now than it was then. He, however, is mistaken in supposing that this consideration has been overlooked by geologists. If he will kindly refer to "Geology," vol. i. p. 440, he will find it there stated, speaking of the older fissure and explosive eruptions, that "there is nothing to show that this [the explosive] action was on the same scale of magnitude and permanence as those of late Tertiary and recent date. With the greater thickness of the earth's crust and the greater resistance presented by its rigidity, volcanic eruptions must with time, as suggested long ago by Elie de Beaumont, have altered with the alterations of those conditions, and may now be exhibited under a phase very different from those of the earlier periods."

Or again, he will find in "The Position of Geology" ("Collected Papers," p. i.) it stated that, though one form of volcanic action (the fissure) was more active in the past than at present, that "explosive eruptions are more violent now than in former times." And again, at p. 145 of the same work, I remark that "while with the thinner crust of former times, there would be a more frequent extrusion of the molten rock, there are probably with the thicker crust now formed and consequently its greater resistance, greater forces stored in the explosive eruptions of the present day."

The instance relied upon by Dr. Wallace is, however, another striking example, if others were needed—though in this case it is on the inverse side as against meteorological agencies—of the non-uniformity *in degree* between the action of the forces of past and present times. The increased thickness of the crust is not, however, the sole cause of the violence of recent eruptions, nor are they, I imagine, due to the presence of occluded water in the volcanic foci. The terrific eruptions of Krakatão and other volcanoes are, I conceive, due simply to the access of vast volumes of surface waters and their sudden flashing into steam.

Volcanic action, therefore, does not seem to me to be in any way in contradiction to the conception of uniformity of *kind* or law, and to non-uniformity on the question of *degree*.

Sevenoaks, May 4. JOSEPH PRESTWICH.

Green Oysters.

I HAVE just received a "Note," extracted from the *Monitore Zoologico Italiano*, of Florence, by Dr. Carazzi, in which a number of unsupported statements are made as to "phagocytosis in Mollusca."

Amongst other statements, I find "Non solo sono osservazioni erronee quelle del Lankester, malamente ripetute dello Chatin, ma lo sono egualmente quelle del Pelseneer e del Bruyne." I am surprised that my zoological friends in Florence should publish a bare statement of this nature without a shred of evidence to support it. I desire to draw attention to the simple assertion made by Dr. Carazzi, and to let those who are responsible know that I and others expect him to show in detail what is the error in the observations published by me on the green oysters of Marennes.

It is certainly not a usual thing for a Society to allow an author to print vague accusations of inaccuracy in reference to other writers, without the smallest attempt to justify such accusations.

Dr. Carazzi's assertion is all the more remarkable, since it appears that he has not examined the true *huîtres de Marennes* at all, and is singularly ill-informed as to the histology and physiology of Mollusca.

I shall be very much surprised if Dr. Carazzi can show that the observations published by me on green oysters in 1886 (*Quart. Journ. Micr. Sci.* vol. xxvi.) are erroneous, and shall at once re-examine the matter if he succeeds in throwing doubt on the facts as stated by me.

Inferences from observed facts stand in a different position from the observations themselves.

I was the first to describe the cells laden with green granules

which occur in the epithelium of the gills and labial tentacles of the Marennes oyster.

I also showed that such cells are present in the common oysters, but that the granules they contain are not green. I further showed that these cells occur abundantly on the *surface* of the gills, crawling about and exhibiting amœboid movement. I also showed that the Marennes oysters are specially fed upon *Navicula ostrearia* which contains a highly refractory blue pigment "Marennin," and I *inferred* that the granular cells of the gills derive their colour from the blue pigment of the naviculæ—since it was shown long ago by Gaillon (in 1824) that the *huitres de Marennes* are purposely placed by the oyster-culturist into tanks containing the *Navicula ostrearia*; that when placed there they have gills of the usual yellow-brown colour, but rapidly acquire the green colour; that they actually feed on the *Navicula ostrearia*, and that when removed from this article of diet, they lose the green colour of gills.

The inference that the "granular cells" are to be regarded as wandering phagocytes, was not first published by me; and, though I have no doubt of its justification, I may point out that it is an interpretation, and not an observation of fact.

Lastly, let me say that I showed by chemical analysis that the green colour of the oyster's gill is *not* due to any metallic base—either copper, iron, or chromium. The statement made by Carazzi that there is "abbondanza di sesqui-ossido di ferro" in the mud of the tanks where the oysters are fed, is therefore doubly futile. Every one knows that such mud contains abundance of iron; but as there is no iron in the green pigment of the oyster, it is useless to draw attention to the iron in the mud. E. RAY LANKESTER.

Oxford, May 4.

The Origin of the Cultivated Cineraria.

I MADE two objections to Mr. Dyer's account of the history of the Cineraria; the careful reader will observe that his letter meets neither. Mr. Dyer informed us that the cultivated Cinerarias were produced "*by the gradual accumulation of small variations*," *i.e.* without the selection of definite sports. My object in adducing historical evidence of Cineraria sports was to prevent Mr. Dyer's pronouncement from being repeated without further evidence. That purpose I think has been attained; for I notice that in now restating his account Mr. Dyer does not refer to the point, though it was the object of his original exhibition of the Cineraria to the Royal Society. That the Cineraria was an excellent "illustration of the amount of variation which could be brought about under artificial conditions in a limited time" I should be the last to dispute. As I showed in my first letter, there is evidence that the time was very short indeed.

Compared with this point, the second question—that of the hybrid origin of cultivated Cinerarias—is of subordinate interest. For the view that they were originally hybrids, resulting from crosses between *C. cruenta*, *C. lanata*, and other species, I have given the evidence, quoting the explicit statement of contemporaries and the almost universal opinion of practical gardeners, with references to the sources of information. Mr. Dyer, however (with him Mr. Rolfe) declares that they are descended from *C. cruenta* alone. Is this statement a mere inference from the want of likeness between particular cultivated Cinerarias and the wild species, or have Mr. Dyer and Mr. Rolfe evidence of a more substantial character? Of course these authorities may be right, and the rest who have written on the matter may be wrong; but I ask for proof of this, and the request can hardly be thought unreasonable.

Mr. Dyer has referred to a remark I made at the meeting respecting the Camellia. At the risk of diverting attention from the real issues, I feel bound to speak of this, for I was then in the wrong. In justice the circumstances must be stated. Speaking of the Cineraria, Mr. Dyer declared that though the flowers have changed so much, the foliage, which had not been an object of Selection, still resembled that of his wild plant. I replied that though this might be true of the Cineraria, it led to no universal induction, for it is well known that the foliage of many plants selected solely for their flowers or for their fruits had varied greatly. As an illustration taken on the spur of the moment, I said that though the matter had not come within my own observation, there was, I believed, a passage in one of Darwin's books to the effect that the foliage of the several kinds of Camellia differed so much that they could be recognised by it alone. Upon Mr. Dyer interjecting that this was not true, I immediately gave up the illustration as not coming within my own knowledge, and substituted that of the Apple, of which I myself know several kinds to have distinct and characteristic foliage. Such examples may be multiplied indefinitely. Now the passage in Darwin is as follows:—"Verlot mentions a gardener who could distinguish 150 kinds of Camellia when not in flower" ("Animals and Plants," ed. 1885, II. chap. xxii. p. 238); but Darwin takes the case as an illustration of the fact that structures "though appearing to an unpractised eye absolutely undistinguishable, yet really differ." My use of this case was therefore a wrong one, and as Mr. Dyer has thought fit again to refer to the matter, I take the opportunity of withdrawing it once more. W. BATESON.

St. John's College, Cambridge, May 5.

The Assumptions in Boltzmann's Minimum Theorem.

MR. CULVERWELL's letter in your issue of April 18 leaves many important points in connection with the reversibility of Boltzmann's Minimum Theorem untouched. On the question as to what different people mean (or think they mean) when they assert that the theorem is true, enough has already been said. What we want to know is what assumptions are involved in the mathematical proofs of the theorem, why they have to be made, and for what systems they are likely to hold. This question has been ably treated by Mr. Burbury, but in view of Prof. Boltzmann's assertion that the theorem is one of probability, it is desirable to examine more fully where probability considerations enter into proofs such as Dr. Watson's, which contain no explicit reference to them.

Dr. Watson starts by assuming two sets of molecules so distributed that the *numbers* having coordinates and momenta within the limits of the corresponding differentials are

$$F(P_1 \ldots Q_m)dP_1 \ldots dQ_m \text{ and } f(p_1 \ldots q_n)dp_1 \ldots dq_n.$$

If, however, the differential elements are taken very small (as when we consider a volume-element comparable with molecular dimensions), these expressions no longer represent numbers of molecules, and it is *assumed* that in this case they represent the *probabilities* of a molecule having coordinates and momenta within the given limits.

It is then necessary to *assume* that *the probabilities for the two kinds of molecules are independent of each other*. This assumption was pointed out to me by Mr. Burbury, and is what I intended to imply in my previous letter when I said that Dr. Watson's assumption was more *natural* than any other. Under these circumstances alone can we assert that the probability of a given combination of coordinates and momenta of *two* molecules is proportional to

$$FdP_1 \ldots dQ_n \times fdp_1 \ldots dq_n$$

To make the proof independent of the choice of coordinates, let $y_1 \ldots y_{m+n}$ be *any other* system of coordinates specifying the *pair* of molecules, so chosen that $y_1 = 0$ at the beginning of an encounter. Then if $x_1 \ldots x_{m+n}$ denote the corresponding momenta, we may employ the theorem proved in my last British Association Report, § 14, to write the above expression in the form

$$FfJdy_1dy_2 \ldots dy_ndx_1 \ldots dx_{m+n}.$$

and if we write $(dy_1/dt)dt$ for dy_1, the probability of a configuration in which an encounter will take place in the time-element dt becomes

$$FfJdy_2 \ldots dx_{m+n}(dy_1/dt)dt$$

corresponding to Watson's expression with (dy_1/dt) in place of (dq_n/dt). This step involves the assumption (made above) that dy_1 is small in comparison with the dimensions of a molecule.

From this point on Dr. Watson's proof is easy. But it will be seen that the probabilities for two molecules are not independent of each other *after* a collision between them. The method would fail if the same pair of molecules were likely to collide repeatedly. Thus the Minimum Theorem depends on the free motions of the molecules quite as much as on the collisions themselves, and it only applies to gases whose molecules mix freely among each other between collisions, not to media where they are densely crowded. In such cases, however, we have Mr. Burbury's investigation (*Phil. Mag.* January 1894).

If we were to reverse the motion exactly, we should have one in which the probabilities for two molecules *before* an

encounter were not independent, and our assumptions (*however improbable*) would be therefore entirely based on our previous experience with the direct motion. Without such assumptions we should have inferred, by the ordinary laws of probability, that H would be likely to decrease. This is what I intended to imply in my previous letter; but as I had used accented and unaccented letters in my statement, I failed to make my meaning clear to Mr. Culverwell, who evidently found it difficult to understand a proof involving their use. G. H. BRYAN.

The Unit of Heat.

I WAS glad to read Prof. Joly's communication in your issue of May 2, for I have made many efforts to call attention to the unsatisfactory nature of our present system of calorimetric measurements, and now that a more powerful voice than mine has been raised in favour of a change, I have some hopes of progress.

The indifference with which, as it appears to me, our physicists regard this matter is probably due to several causes. They ignore the fact that the science of calorimetry has recently made great strides, and that an ambiguity as to the unit, which formerly was of little consequence, has now become almost the only bar to further progress; also, as Prof. Joly has pointed out, our system of calorimetric measurements has been so wedded to the method of mixtures, that the union has (wrongly) come to be regarded as essential.

As to Prof. Joly's proposal, there is much to be said in its favour. It is practical and definite. At the same time the change would be so radical, that I should not feel justified in counting myself as his disciple in this matter without serious consideration.

My own inclination is rather in the direction of a C.G.S., or absolute unit, and the course adopted by Prof. Schuster and Mr. Gannon, in entitling their recent important communication to the Royal Society "The Specific Heat of Water," rather than the "Mechanical Equivalent of Heat," shows that a step has already been taken in this direction.

When we reflect on the attention and the labour which have been devoted to the establishment of our present system of electrical units, it is a cause for wonder that so important a unit as that of heat should have been left ill-defined and unregarded.

I would propose that at the forthcoming meeting of the British Association, the attention of Section A should be particularly directed to this matter; and it would prepare the way for such action if those who have definite proposals to make would, in the meantime, communicate them to your columns.

Cambridge. E. H. GRIFFITHS.

REFERRING to Dr. Joly's letter last week, would it not be well definitely to adopt the "Joule" as the only fundamental unit of heat, and to realise distinctly that researches such as those of Mr. Griffiths, Prof. Rowland, and Dr. Joly are determinations of the specific heat of water and of the latent heat of steam in terms of it? OLIVER J. LODGE.

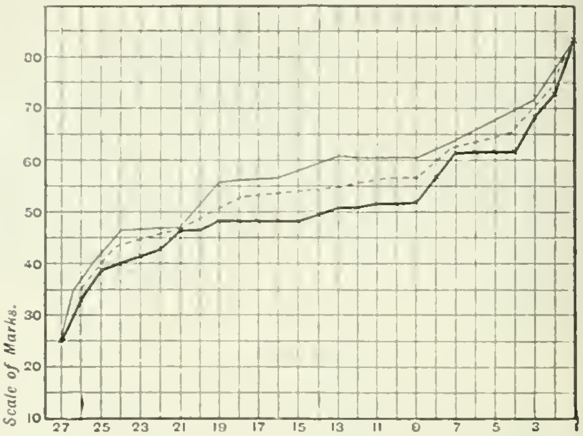
The Examination Curve.

THE extremely interesting article, by Prof. Lloyd Morgan (vol. li. pp. 617–619), on the graphic representation of the marks given in an examination, and of their great use to an examiner, leads me to ask whether even this method may not be developed further with advantage to all concerned, for, as Lloyd Morgan says: "If, after an extensive set of papers has been looked over and carefully marked, an interval of time be allowed to elapse, and then the papers are gone over again, the result of this re-examination is that the head and tail remain practically unchanged, but that there is not a little redistribution among the mediocrities." In other words, the personal equation of the examiner varies, showing itself mostly in the middle of the curve.

The first thing to strike me on looking at Fig 2 (vol. li. p. 618), was the great similarity of the two halves of the curves, and on tracing it, and then turning the tracing half round so that the upper end of the traced curve became superimposed upon the lower end of the original, and *vice versa*, the similarity was so marked as to make one think, that had a larger number of papers been examined and as carefully marked as the first set, the traced curve would have covered the other.

If such be the case, why should not the examiner, after plotting the marks he thinks best, make a tracing of the curve, then reverse it, superimposing the two ends as before, and sketch it in alongside his first curve (easily done by means of oil-paper), then, if they differed, draw a fresh curve midway between the two: subsequently re-marking his examination papers from this smoothed mean curve? An illustration may be of use: let it be founded on Fig. 1, as it contains the less smooth curve. The dark line is that of the marks first adjudged; the light line, the same curve reversed; and the dotted line, the smoothed mean curve of the two from which his papers are finally marked.

Granting that the plus variations and the minus variations on the two sides of the mean nearly balance, the question would appear to be—Would one be justified in smoothing them in accordance with the generalised results of many such series? It involves some forcing of the examiner's marking into the general mould, but would this be more than sufficient to correct



Examinees. FIG. 1.

his personal equation? On the other hand, the two halves—say from paucity of examiners—might be so dissimilar, that the mean curve would differ very much from the original form. In this case, would it be possible to give any general rule whereby one could be guided whether to adopt the mean curve, or to remain satisfied with the original marks given?

In Herbert Spencer's "Principles of Sociology," (vol. i. p. 88) are many references to the fact that "the children of Australians, of Negroes in the United States, of Negroes on the Nile, of Andamanese, of New Zealanders, of Sandwich Islanders [and others], are quicker than European children in acquiring simple ideas, but presently stop short from inability to grasp the complex ideas readily grasped by European children, when they arrive at them." F. HOWARD COLLINS.

April 29.

Teaching Young Pheasants to Peck.

IT may interest Prof. Lloyd Morgan and others to know that when Assamese find newly hatched chicks in the jungles, they have a system of teaching the little ones to peck and pick up food, without which, I am told, many of them would die.

Walking down a road one morning with a neighbour, we suddenly noticed a little ball of fluff between my feet, and I could hardly avoid stepping on it, as it stuck close to me; almost immediately another appeared at my friend's feet, and we saw they were newly-hatched pheasants, the mother probably carried off by some wild cat.

As it was difficult to walk with these little things running so close and in the way, we lifted them into the short grass alongside, and hurried on some fifty yards.

On returning we had forgotten them, but one ran out, and so pertinaciously stuck to my boots, that to save it I put it into my pocket, and on our arrival at the bungalow tried to feed it with small fragments of hard-boiled egg, rice, and white ants. Of all these it took no notice.

Next morning the other chick was found at the foot of the bungalow steps, having probably followed us unnoticed the day before. I then called my "Babu," as I could not get them to eat, and he said "they must be *taught*."

He put the gauze wire cover they were under, and the crushed

rice, egg, &c., on a hard wood table, and taking a pencil from his pocket and collecting the eatables together, close to the edge of the gauze cover, he lifted its edge, and with the pencil point inserted, began sharply tapping among the rice débris. The two chicks at once ran over to that place and bent over, watching the tapping, and to our astonishment they began tapping with their little beaks the same way, and before long had begun to feed on their own account, just as the "Babu" had predicted; and after that lesson we had no trouble.

As I happen to be writing, I may mention that our land lizard (3 feet 6 inches to 4 feet 6 inches total length, name unknown to me) has begun calling in the early dawn and dusk at evening. It is silent during the day and night.

From the bearings taken, it can be heard plainly at a mile in forest, and often five or six calling at once in different directions. The native Asamese name is "Gui," which is precisely the sound it makes; by the old spelling it is "Gooee." S. E. PEAL.

Sibsagar, Asam, April 4.

The Bagdad Date-mark.

THERE will be found in Grattan Geary's "Through Asiatic Turkey" all about the date-mark—a mysterious and troublesome excoriation, coming only once, but which lasts a year, leaving an ugly scar the size and outline of the fruit—visitors for any length of time at Bagdad seldom, and residents never, escape. It is also known at Aleppo and other places, but is worst in Bagdad, almost every native being marked. Even nitric acid has been found to have little effect upon it. I lately spent forty-four days, off and on, at Bagdad, and imagined I had escaped: not so, however, as it proved six weeks after my return to India. But the mark yielded forthwith, and before any damage was done, to hyposulphite of soda, which does so much "fixing" for every amateur photographer, and seemed worth trying. The fact may be usefully mentioned in the interest of Mesopotamian explorers who do not want to be date-marked as a memento; but it is to physiologists they must look for an explanation.

Bombay, April 12. A. T. FRASER.

THE ROYAL SOCIETY SELECTED CANDIDATES.

THE following are the names and qualifications of the fifteen candidates recommended by the Council of the Royal Society, on Thursday last, for election into the Society.

J. WOLFE BARRY,

C.B., Civil Engineer. Vice-President of the Institution of Civil Engineers. Is eminently distinguished in his profession, and has designed and executed many works of national importance, which include the Tower Bridge, opened by H.R.H. the Prince of Wales, 1894; the City Terminus extension of the Charing Cross Railway, the Inner Circle Railway, and the Barry Dock. Has served as a member of the following Royal and Departmental Commissions:—Royal Commission on Irish Public Works, 1887; Highlands and Islands of Scotland Commission, 1890; Commission on the River Ribble, 1891; Thames Navigation Commission, 1894. Member de la Commission Consultative des Travaux de la Campagnie Universelle du Canal Maritime de Suez. Is the author of many papers, mainly in reference to engineering works, which have been published in the *Transactions of the Institution of Civil Engineers* and elsewhere. Is the author of several professional treatises, among which the following are the more important: "The Barry Dock" (British Association Report, 1888): "Railway Appliances," "Railways and Locomotives," published in conjunction with Sir F. Bramwell, Bart.

ALFRED GIBBS BOURNE,

D.Sc. (Lond.), Professor of Biology in the Presidency College, Madras. Fellow of University College, London. For many years engaged in teaching and in researches upon Comparative Anatomy and Embryology, especially of Invertebrata. Especially known to comparative anatomists for his discoveries in the structure of leeches, and as discoverer of the hydroid phase of Limnocodium, also of two remarkable new genera of Chætopod worms, described by him as Haplobranchus and Chætobranchus. Author of the following, as well as several other memoirs: "On the Structure of the Nephridia of the Medicinal Leech" *Quart. Journ. Micros. Sci.*, 1880); "Contributions to the Anatomy of the Hirudinea" (*ibid.*, 1884); "On the Hydroid Form of Limnocodium" (*Proc. Roy. Soc.*, 1884): "On the Supposed Communication of the Vascular System with the Exterior in Pleurobranchus" (*Quart. Journ. Micros. Sci.*, 1885). Since he has been in India, Prof. Bourne has sent home important researches on Indian Earthworms, on Chætobranchus (a new naidiform worm), on a new Protozoon of the genus Pelomyxa, with observations on the structure of protoplasm, and some valuable experimental researches on the suicide of Scorpions (*Proc. Roy. Soc.*, 1889).

GEORGE HARTLEY BRYAN,

M.A., Fellow of Peterhouse, Cambridge. Lecturer (on Thermodynamics, &c.) on the University list. Fifth Wrangler, 1886; Class I, Division 1, 1887; bracketed with Senior Wrangler, Smith's Prize, 1888, for the Essay "On the Curves on a Rotating Spheroid of Finite Ellipticity" (*Phil. Trans.*, 1889 A). Author of the following papers:—"On the Stability of a Rotating Spheroid of Perfect Fluid" (*Proc. Roy. Soc.*, vol. xlvii.); "On the Stability of Elastic Systems"; "Waves on a Viscous Rotating Cylinder" (*Proc. Camb. Phil. Soc.*, vol. vi.); and several others in *Phil. Mag.*, *Proc. Lond. Math. Soc.*, and *Proc. Camb. Phil. Soc.*, &c. Also joint author, with Mr. Larmor, of the Report on Thermodynamics, published in the British Association Reports, 1891.

JOHN ELIOT,

M.A. (Cantab.), Meteorological Reporter to the Government of India. Late Meteorological Reporter to the Government of Bengal. Was Second Wrangler and Smith's Prizeman, 1869. Mr. Eliot, as Meteorological Reporter to the Government of Bengal, and subsequently as Head of the Meteorological Department of India, has made many important additions to the physical data of Indian meteorology, and has done much in their utilisation, and in the improvement of the administration of the department of which he is now the head. Under him have been carried out the publication of Daily Weather Charts for the Bay of Bengal and Calcutta, for Bombay and the Western Coasts of India, and general charts for the whole peninsula. He has also organised the systematic collection of marine observations from ships arriving at the chief Indian ports. His special work, contained in a long series of memoirs, published either in separate form by the Meteorological Department, or in the *Journal of the Asiatic Society of Bengal*, chiefly relates to storms in India and Indian seas, and comprises complete histories and discussions of fifteen cyclones and upwards of one hundred storms that have occurred between 1877 and 1886. The Annual Reports of the Meteorological Department, prepared by him, also contain many valuable and original discussions. He has contributed very largely to establish the Indian Meteorological Department on a thoroughly scientific basis, and to maintaining its high character and recognised practical importance to our great Indian dependency.

JOSEPH REYNOLDS GREEN,

D.Sc. (Cantab.), M.A., B.Sc. (Lond.), F.L.S. Professor of Botany, Pharmaceutical Society of Great Britain. Distinguished for his acquaintance with botany. Attached to science, and has contributed to its progress by discoveries in the region of physiological chemistry, with reference chiefly to plants. His more important contributions are contained in the following papers:—"On the Organs of Secretion in the Hypericaceæ" (*Journ. Linn. Soc.* (*Bot.*), vol. xx., 1883); (with Dr. Sheridan Lea) "Some Notes on the Fibrin-ferment" (*Journ. of Physiol.*, vol. iv., 1883); "On the Edible Bird's Nest of the Java Swift" (*ibid.*, vol. vi., 1885); "On Proteids occurring in Latex" (*Proc. Roy. Soc.*, 1886); "On the Action of Sodium Chloride in dissolving Fibrin" (*Journ. of Physiol.*, vol. viii., 1887); On Certain Points connected with the Coagulation of the Blood" (*ibid.*); "On the Changes in the Proteids of the Seed which accompany Germination" (*Phil. Trans.*, 1887); "On the Germination of the Tuber of the Jerusalem Antichoke" (*Annals of Botany*, vol. i., 1888): "On the Germination of the Seed of the Castor-oil Plant" (*Proc. Roy. Soc.*, 1888); "On the Occurrence of Diastase in Pollen," (Brit. Assoc. Report, 1891); "On the Occurrence of Vegetable Trypsin in the Fruit of *Cucumis utilissimus*" (*Annals of Botany*, vol. vi., 1892); (with Prof. Vines) "On the Reserve Proteid of the Asparagus Root" (*Proc. Roy. Soc.*, 1892); "On the Ger-

mination of the Pollen-grain and the Nutrition of the Pollen-tube" (*Phil. Trans.*, 1894): "On Vegetable Ferments" (*Annals of Botany*, vol. vii., 1893); "On the Influence of Light on Diastase" (*ibid.*, vol. viii., 1894).

ERNEST HOWARD GRIFFITHS,

M.A. Private Tutor. Author of the following papers:—"On the Comparison of Platinum Temperatures with the Kew Standard" (Rept. of Committee on Electrical Measurements, Brit. Assoc., 1890); "On the Determination of certain Boiling and Freezing Points" (*Phil. Trans.*, 1891 A); "The Electrical Resistance of Platinum Wire at Absolute Zero" (*Phil. Mag.*, Dec., 1892); "On the Determination of Low Temperatures by Platinum Thermometers" (*Proc. Camb. Phil. Soc.*, vol. viii., Part I.); "On the Increase in Resistance of a Conductor when Transmitting a Current" (*ibid.*, vol. viii., Part I.); "The Mechanical Equivalent of Heat, together with an Investigation into the Changes in the Capacity for Heat of Water" (*Phil. Trans.*, 1893 A); "The Boiling Point of Sulphur, together with a Method of Standardising Platinum Thermometers," jointly with Mr. Callendar (*Phil. Trans.*, 1891 A).

Supplementary Certificate. Appendix to the communication entitled "The Mechanical Equivalent of Heat" (*Proc. Roy. Soc.*, vol. lv., 1893); "A Method of Joining Glass and Metal Tubes" (*Proc. Phil. Soc. Camb.*, 1893); "The Measurement of Temperature" (*Science Progress*, 1894); "The Influence of Temperature on the Specific Heat of Aniline" (*Phil. Mag.*, 1895); "The Latent Heat of Evaporation of Water" (read Royal Society, January 1895).

CHARLES THOMAS HEYCOCK,

M.A., Lecturer on Natural Science, King's College, Cambridge. Author of "Revision of the Atomic Weight of Rubidium" (Brit. Assoc. Rept., 1882); joint author of: "Spectrum of Indium" (*Phil. Mag.* [5] I., 1876); "On a Simplified Form of Apparatus for Determining the Density of Ozone" (*Proc. Camb. Phil. Soc.*, v.); "Lowering of the Freezing Point of Tin by the Addition of other Metals" (*Proc. Chem. Soc.*, No. 65, 1889); "Lowering of the Freezing Point of Sodium by the Addition of other Metals" (*Trans. Chem. Soc.*, lv., 1889); "Molecular Weights of Metals when in Solution" *ibid.* (lvii.); "Freezing Point of Triple Alloys of Gold, Cadmium, and Tin" (*ibid.*, lix.); "Lowering of the Freezing Points of Cadmium, Bismuth, and Lead, when alloyed with other Metals" (*ibid.*, lxi.); "Isolation of a Compound of Gold and Cadmium" (*ibid.*); "Freezing Point of Alloys in which Thallium is the Solvent" (*ibid.*, 1894); "Freezing Point of Triple Alloys" (*ibid.*); "Change in the Zero of Mercury Thermometers" (*Proc. Camb. Phil. Soc.*, vii.).

SYDNEY JOHN HICKSON,

D.Sc. (Lond.), M.A. (Cantab.), Hon. M.A. (Oxon.), F.Z.S. Fellow of Downing College, Cambridge. Author of papers published in the *Philosophical Transactions*, "On the Ciliated Groove (Siphonoglyphe) in the Stomodæum of the Alcyonarians" (1883); "On the Sexual Cells and Early Stages in the Development of *Millepora plicata*" (1888). In the *Quart. Journ. Micros. Sci.*, "The Eye of Pecten" (1880); "The Eye of Spondylus" (1882); "The Structure and Relations of Tubipora" (1883); "The Eye and Optic Tract of Insects" (1895). In the *Tijdschr. van het Nederl. Aardrijkskund. Genootsch.*, "Omzwervingen in Noord-Celebes" (1887). In the *Journ. Anthrop. Inst.*, "Notes on the Sengirese" (1886). Author of the work, "A Naturalist in North Celebes."

HENRY CAPEL LOFFT HOLDEN,

Major, Royal Artillery. In India from 1877–84, he carried out a number of experiments in telephony and telegraphy for the Indian Government. Since 1885 he has been in charge of the Department for the proofs of Naval and Land Service Ordnance, and Gunpowders, and for experiment work connected therewith, and has invented and constructed many pieces of apparatus connected with the science of artillery, as well as with electrical and scientific research. Amongst those which have been publicly exhibited are his devices in connection with the chronograph, for measuring the velocity of projectiles; an extremely accurate and sensitive hydrometer for measuring the variations of the density of the acids in the electrolyte accumulator cells (exhibited Royal Society, 1887; see also paper before Iron and Steel Inst., 1891); a high-speed chronographic pen for recording minute intervals of time by electromagnetic means; various instruments for making accurate and rapid tests of the pressure and current in direct current circuits, and in alternating current circuits of both high and low frequency (some exhibited Royal Society, 1892); an instrument for rapidly ascertaining the E.M.F. and resistance of a galvanic cell (exhibited Royal Society, 1893); a compact moving coil galvanometer adapted to universal purposes, which was employed by Profs. Dewar and Fleming in their researches on the resistance of metals, and is used in the recording pyrometer of Prof. Roberts-Austen. He was deputed by the Commander-in-Chief to write the electrical sections of the Paris Exhibition of 1889, the Frankfort Exhibition of 1891, and the Chicago Exhibition of 1893, and furnished the Government with most valuable reports.

FRANK McCLEAN,

M.A., LL.D. (Glasg.), F.R.A.S., M.I.C.E. Author of "Photographs of the Red End of the Solar Spectrum from D to A" (*Monthly Notices*, vol. xlix.); "Parallel Photographs of the Sun, Iron, and Iridium, from H to near D" (*ibid.*); "Comparative Photographs of High and Low Sun H to A, with Notes on the Method of Photographing the Red End of the Spectrum" (*ibid.*, vol. li.); "Comparative Photographs of Sun and Metal Spectra" (Series 1 and 2, *ibid.*, vol. lii.). Inventor of McClean's Star Spectroscope, an invaluable aid in the study of stellar spectra. Attached to science, and anxious to promote its progress. Founder of the Isaac Newton Scholarship at Cambridge. Donor of a large telescope to the nation, to be used in physical inquiries at the Royal Observatory, Cape of Good Hope.

WILLIAM MACEWEN,

M.D. (Glasg.), Hon. LL.D. (Glasgow). Professor of Surgery, University of Glasgow. A distinguished Surgeon. Author of: "Observations concerning Transplantations of Bone, &c." (*Proc. Roy. Soc.*, May 1881, and *Comptes rendus* Acad. Sci., Paris, June 1881); "Treatise on Osteotomy" (London, 1880; translated into French, German, Italian, Roumanian, Swedish and Russian); "Osteogenic Factors in the Development and Repair of Bone" (*Annals of Surgery*, 1887); Address on the Surgery of the Brain and Spinal Cord (*Lancet*, and *Brit. Med. Journ.*, 1888); "The Pupil in its Semiological Aspects" (*Internat. Journ. of Med. Sciences*, 1887); "Radical Cure of Hernia" (*Annals of Surgery*, 1886); also numerous articles on special points in Surgery.

Supplementary Certificate. Author of a treatise on Pyogenic Infective Diseases of the Brain and Spinal Cord (1893); an Atlas of Head Sections, with fifty-three copper plates, fifty-three key plates and descriptive text (1893). Especially distinguished for his work on the Surgery of the Bones and in the Development and Practice of the Surgery of the Brain and Spinal Cord.

SIDNEY MARTIN,

M.D., B.S., B.Sc., F.R.C.P. Assistant Physician, University College Hospital, and Hospital for Consumption, Brompton. Distinguished for researches in chemical physiology and pathology; has carried out researches on chemical bacteriology for the Local Government Board, and for the Royal Commission on Tuberculosis. The following are his principal published papers:—"Papain Digestion" (*Journ. of Physiol.*, v.); "Nature of Papain and its action on Vegetable Proteids" (*ibid.*, vi.); "The Proteids of the Seeds of *Abrus precatorius*" (*Proc. Roy. Soc.*, xlii.); "Physiological Action of the Active Principle of *Abrus precatorius*" (*ibid.*, xlvi.); "The Toxic Action of the Albumose from the Seeds of *Abrus precatorius*" (*ibid.*); "Gluten and the Proteids of Flour" (*Brit. Med. Journ.*, 1886); "The Influence of Bile on Digestion" (with Dr. D. Williams—*Proc. Roy. Soc.*, xlv. and xlviii.); "The Chemical Products of the Growth of *Bacillus anthracis* and their Physiological Action" (*ibid.*, xlviii.); "Preliminary Report on the Chemical Products of the Life of *Bacillus anthracis*" (Rept. of the Med. Officer, Local Govt. Board, 1889–90); "Chemical Pathology of Anthrax" (*ibid.*, 1891); "Diphtheritic Paralysis" (*Proc. Roy. Soc.*, 1892); "Gulstonian Lectures on the Chemical Pathology of Diphtheria compared with that of Anthrax, Infective Endocarditis and Tetanus," 1892; "Two Classes of Vegetable Globulins" (*Proc. Physiol. Soc.*); "Pathology of the Proteids of the Body" (*Brit. Med. Journ.*, 1890).

GEORGE M. MINCHIN,

M.A. (Dubl.), Professor of Mathematics in the Royal Indian Engineering College, Cooper's Hill. Author of the following treatises: "Statics," "Uniplanar Kinematics," and "Hydro-

statics." Also of the following papers:—"Astatic Equilibrium of any System of Forces, treated by Quaternions" (*Proc. Lond. Math. Soc.*); "The Absolute Sine Electrometer" (*Nature*, *Electrical Review*, &c.); "Researches in Photo-electricity" (*Proc. Phys. Soc.* and *Phil. Mag.*): "Impulsion Cells" (*Electrician*, *Proc. Phys. Soc.*); "Seleno-Aluminium Cells and the Electromotive Forces of Starlight" (*Astronomy and Astro-Physics*); "The Magnetic Field of a Circular Current"; "The Magnetic Field close to the Surface of a Wire carrying a Current" (*Phil. Mag.*, *Proc. Phys. Soc.*).

WILLIAM HENRY POWER,

Assistant Medical Officer, H.M. Local Government Board. Author of Reports to the Local Government Board relating to the natural history of epidemic diseases and materially extending the knowledge thereof, more especially (*a*) Demonstration in 1882 of the existence of Scarlatinal Disease in Cows, explaining the previously obscure spread of Scarlatina in human communities by means of Cow's Milk; (*b*) Record of Cases (afterwards followed by Dr. Klein) where Diphtheria had been spread by the consumption of Cow's Milk; (*c*) Discovery, in 1881, of the ability of Smallpox to extend atmospherically (without other personal relation) from a hospital to houses in its neighbourhood. The subject was investigated by a Royal Commission which recognised the facts; they have been subjected to further demonstration by Mr. Power during subsequent years.

THOMAS PURDIE,

B.Sc., Ph.D., A.R.S.M., Professor of Chemistry in the University of St. Andrews. Author of the following:—"On the Synthesis of α Isoheptane"; and "On the Action of Sodium Alcoholates on Fumaric Ethers" (*Trans. Chem. Soc.*, 1881); "Action of Sodium Alkyl Oxides on Ethereal Fumarates" (*ibid.*, 1885); "The Action of Metallic Alkylates on Mixtures of Ethereal Salts with Alcohols" (*ibid.*, 1887). Joint author with W. Marshall, B.Sc., of:—"Action of Alcohols on Ethereal Salts in presence of Small Quantities of Sodic Alkylates" (*Trans. Chem. Soc.*, 1888); "The Addition of the Elements of Alcohol to the Ethereal Salts of Unsaturated Acids" (*ibid.*, 1891). Joint author with J. Wallace Walker, M.A., of:—"Resolution of Lactic Acid into its Optically Active Components" (*ibid.*, 1892); "Optically Active Ethoxysuccinic Acid" (*ibid.*, 1893).

APRIL METEORS.

COMPARATIVELY few meteors of the April shower appear to have been seen this year in consequence of the cloudy weather which prevailed. But if the results are scanty they are interesting, for three fine meteors were observed at more than one station, and their real paths in the atmosphere have been computed.

On April 14, 11h. 44m., a bright first mag. meteor was seen by Prof. A. S. Herschel at Slough, and by the writer at Bristol. It moved rapidly in a rather long path, and left a bright streak. The radiant point is indicated at $316° + 31°$ near ζ Cygni, and the meteor fell from 87 to 71 miles over the English Channel. During its visible career it traversed a course of 107 miles with a velocity of about 49 miles per second. The radiant of this meteor near ζ Cygni is almost identical with that ($314° + 27°$) found for a 1–2 mag. meteor observed on April 20, 1893, also by Prof. Herschel and the writer.

On April 19, 10h. 59m., a fine meteor, variously estimated as = 1st mag., 2 × ♃, = ♀, = 1st mag., was observed by Mr. Corder at Bridgwater, Mr. Blakeley, Dewsbury, Mr. Packer, Birmingham, and the writer at Bristol, respectively. Its motion was moderately slow, and it left a streak. The direction of its flight shows it to have been a Lyrid with a radiant at $269° + 30°$. The meteor descended from 91 to 43 miles over the North Sea and Lincolnshire, and traversed a path of 97 miles with a velocity of 33 miles per second. This object appeared much brighter to the observers at Birmingham and Dewsbury than to those at Bridgwater and Bristol, for the meteor was far more distant from the latter places, and its light much veiled in the mist lying over the stars of Cygnus near the north-east horizon.

On April 19, 11h. 46m., another conspicuous meteor, moving very swiftly, and leaving a bright streak, was seen in Hercules and Boötes by Mr. Corder at Bridgwater, and the writer at Bristol. Its radiant was in Sagitta at $300° + 20°$. The meteor fell from 77 to 71 miles over Wiltshire and Somerset, and travelled along a path of 40 miles in less than one second of time. The radiant in Sagitta furnishes a well-defined meteor shower at the April epoch, and I first detected it in 1877. My positions for the radiant are as follow:

D, 92 ...	1877, April 16–19 ...	$298 + 25$	6 meteors
D, 110 ...	1885, April 18–20 ...	$299 + 24$	5	,,
D, 121 ...	1887, April 19–25 ...	$302 + 23$	4	,,

The mean position is at $300° + 24°$. Mr. Corder saw a shower in April–May 1876–9 from $300° + 20°$ (7 meteors), which presents an excellent accordance. The meteors of this stream are very swift, and commonly germinate streaks; but the shower is not well displayed until the morning hours, the radiant being very low before midnight. W. F. DENNING.

NOTES.

THE following fifteen candidates were selected on Thursday last by the Council of the Royal Society, to be recommended for election into the Society:—Mr. J. Wolfe Barry, Prof. A. G. Bourne, Mr. G. H. Bryan, Mr. J. Eliot, Prof. J. R. Green, Mr. E. H. Griffiths, Mr. C. T. Heycock, Prof. S. J. Hickson, Major H. C. L. Holden, Mr. F. McClean, Prof. W. MacEwen, Dr. S. Martin, Prof. G. M. Minchin, Mr. W. H. Power, Prof. T. Purdie. We give the qualifications of the candidates in another part of this number.

THE memorial of the late Prof. J. C. Adams, at Westminster Abbey, will be unveiled this afternoon by the Duke of Devonshire.

WE are glad to be able to report that Prof. Huxley has been steadily improving in health during the past few days.

DR. P. DANGEARD has been appointed Professor of Botany to the Faculty of Sciences at Poitiers.

AT a meeting of the Court of the Spectacle Makers' Company, on Thursday last, Mr. W. H. M. Christie, the Astronomer Royal, was presented with the honorary freedom of the Company, in recognition of his services to astronomical science.

THE De Candolle prizes have been awarded by the Physical and Natural History Society of Geneva to Dr. O. Warburg for his monograph of the *Myristicaceæ*, and to Dr. R. von Wettstein for his monograph of the genus *Euphrasia*.

DURING the past week, the deaths of several eminent men of science have occurred. Surgeon-Major Carter, who was elected a Fellow of the Royal Society in 1859, and obtained the Royal Medal in 1872, died on Saturday last, the 4th inst., at his residence in Budleigh Salterton. We notice also the death of Mr. A. E. Durham, late Vice-President of the Royal College of Surgeons of England, and the author of numerous works on subjects connected with medicine and surgery. Among the announcements of deaths abroad, we regret to see the name of Prof. K. Ludwig, Professor of Physiology in the University of Leipzig, and Director of the Physiological Institute there. He was seventy-eight years of age. The death is also announced of Prof. Manuel Pinheiro Chagas, General Secretary of the Royal Academy of Sciences at Lisbon. Prof. Chagas was born November 13, 1842.

Dr. Karl Vogt, the eminent biologist, died at Geneva on Monday, at seventy-eight years of age. He was born at Giessen, and studied under Liebig and Agassiz. After residing for a time in Paris, he returned to Germany, in 1847, as Professor of Zoology in the University of his native town, but soon lost his chair for political reasons. In 1852 he became Professor of Geology at Geneva, and from that time identified himself with the civic life of the country of his adoption.

We regret to notice that Sir George Buchanan, formerly medical officer to the Local Government Board, died on Sunday last, at the age of sixty-four. As mentioned in these columns last week, he was chairman of the Royal Commission on Tuberculosis, the report of which has just been published. His contributions to the literature of preventive medicine, hygiene, and sanitation are numerous and of prime importance. He was elected a Fellow of the Royal Society in 1882.

On Monday, May 20, a meeting will be held at the Royal Geographical Society to commemorate the fiftieth anniversary of the sailing of the Arctic Expedition, under Sir John Franklin. The Society's anniversary meeting and the annual conversazione will be held on the following Monday, May 27.

The Earl of Selborne, whose death occurred on Saturday last, was elected a Fellow of the Royal Society in 1860. He was raised to the peerage as Baron Selborne in 1872. The little Hampshire village, from which the title was derived, is that which is immortalised by Gilbert White's "Natural History."

The Department of Science and Art has received, through the Foreign Office, a programme of an Exhibition of Medicinal and Useful Plants, which is to be held at the Hague in July next. Intending exhibitors may obtain further information from Dr. M. J. Greshoff, 97 Laan van Meerdervoort, at the Hague.

Sixty-six natives, and as many as 252 animals, have been brought over from Somaliland by Herr Menges, for the East African Village at Sydenham. Among the animals was a "Waller" antelope, and numerous lions, cheetahs, hyenas, jackals, baboons, and ostriches. A further instalment of twenty lions, eleven elephants, four zebras, nineteen ostriches, six leopards, four pythons, and other animals will shortly arrive.

An International Health Exhibition is to be opened in Paris in a few days, and is to remain open until September 15 next. The exhibits are divided into ten groups, as follow:—(1) Hygiene of the house; (2) the health of towns; (3) treatment of infectious diseases; (4) demography and sanitary statistics; (5) sanitary science; (6) hygiene of infancy; (7) industrial and professional hygiene; (8) food products; (9) the hygiene of clothing—laundry work, sanitary clothing, &c.; (10) physical exercise.

A course of lectures on "Our Edible Sea Fish and the Sea Fisheries," to be delivered by Prof. W. A. Herdman, F.R.S., at University College, Liverpool, has been arranged by the Lancashire Sea Fisheries Joint Committee. The object of the lectures is to interest and inform the general public in a matter of national importance, viz. the present position and future prospects of our fisheries, the need of protection and regulation, and the benefits which may be expected to result from such operations and from fish-hatching and shell fish culture.

The library of the Marine Biological Association's laboratory at Plymouth is in want of a number of volumes to complete sets of those books which form an essential part of the equipment of an institution where scientific investigation is carried on. Among the volumes badly needed are: *Philosophical Transactions* previous to 1878, and the *Proceedings* of the Royal Society previous to 1888. Fellows of the Royal Society, who do not wish to keep their old *Transactions* and *Proceedings*, or the families of Fellows who are dead, could not bestow those volumes more worthily than by giving them to the Plymouth Laboratory. Other volumes which would be welcomed are: *Proceedings* of the Zoological Society previous to 1891, and the *Zeitschrift für Wissensch Zoologie* previous to 1875. Any special monographs on biological subjects, or separate copies of papers, would also be gladly received. Every man of science knows that the literature of a subject should be easy accessible to an investigator, and will therefore recognise the necessity of making the library at Plymouth less deficient in works of reference than it is at present.

We gave last week a list of the new officers of the U.S. National Academy of Sciences, elected at the recent annual meeting. The new members elected at the same meeting were—Dr. William H. Welch of Johns Hopkins University, Dr. William L. Elkin of Yale University, Prof. Charles S. Sargent of Harvard University, and Prof. Charles Whitman of Chicago University. Three foreign associates were chosen—Prof. Rudolph Leuckart of the University of Leipzig, Prof. Julius von Sachs of Wurzburg, and Prof. Sophus Lie, of Leipzig. The Barnard gold medal was voted to Lord Rayleigh for the discovery of argon. The Watson medal and a purse of 100 dollars was presented to Prof. L. C. Chandler for his researches on the variation of latitude and on the variable stars. An account of this award was given in Nature a year ago (vol. 50, p. 157). A list of the papers read at the meeting will be found among our Reports of Societies. The Academy selected Philadelphia as the place for the autumn meeting, and fixed the date at October 29. At that meeting the new president, Prof. Wolcott Gibbs, will be inducted into office, and Prof. O. C. Marsh's term of office will terminate.

A new era of cheap telephoning seems to have followed the expiration of certain patents and the judicial annulment of others in the United States a few months ago. Simultaneous announcements of reduced rates in Connecticut and Illinois coincide with the formation of a new company—the Standard Telephone Company—with ramifications or sub-companies extending all over the United States, and an aggregate capital of 160,000,000 dollars. Preliminary arrangements were very quietly made, but this company now comes forward with rates of 3 dollars a month, instead of many times that amount now charged, in some cases running as high as 240 dollars a year. Efforts have been made, to induce the legislature of the State of New York, to secure a compulsory reduction of rates; but the old companies have opposed such legislation strenuously, on the ground that no cheaper service could be given. The Standard Company, however, claim to have discovered a new principle or method of operating in electricity, which will enable them to converse over unprecedented distances—say from New York to Denver, or even San Francisco—at very moderate cost. The reticence maintained, however, makes it impossible to decide whether or not these extravagant claims are well-grounded.

At the second International Zoological Congress held in Moscow in 1892, a resolution was passed to the effect that the third meeting should take place in Leyden, the oldest University of the Netherlands, and that Dr. F. A. Jentink, Director of the Leyden Natural History Museum, should be its President. A circular informs us that the Netherlands' Zoological Society is making the necessary arrangements for this meeting, which is to be held on September 16–21, under the patronage of the Queen-Regent of the Netherlands. The Ministers of the Interior, of the Public Works, and of Commerce and Industry, will be Honorary Presidents of the Congress. A number of well-known

zoologists have promised to attend the meeting, and to deliver addresses or read papers. The following scheme for the sectional meetings has been arranged :—(1) General zoology ; geographical distribution, including the fossil faunas ; the theory of evolution. (2) Classification of living and extinct vertebrates ; bionomy ; geographical distribution, including fossil vertebrates. (3) Comparative anatomy of living and extinct vertebrates ; embryology. (4) Classification of living and extinct invertebrate animals ; bionomy. (5) Entomology. (6) Comparative anatomy and embryology of invertebrate animals. Intending members may send the subscription (£1) to Dr. P. P. C. Hoek (Helder), the General Secretary, or to Dr. R. Horst (Leyden), Treasurer.

The summer meetings of the Institution of Naval Architects will be held in Paris on Tuesday, June 11, and during the remainder of the week. The Right Hon. Lord Brassey, K.C.B., President of the Institution, will occupy the chair. We are informed that the French Government is taking a warm interest in these meetings, and that, under the honorary presidency of the Minister of Marine, Vice-Admiral Besnard, and under the acting presidency of Vice-Admiral Charles Duperré, a strong and influential Reception Committee has been formed, representing the Ministry of Marine, the French Navy, the Municipality of Paris, the Chamber of Commerce of Paris, the Great French Industries and Steamship Owners, the Railroad Companies, the University of Paris, the Conservatoire des Arts et des Métiers, the French Institution of Civil Engineers, the Society for the Encouragement of National Industry, the French Institution of Naval Architects, and the Union of Yachts. This Committee has already taken active steps to draw up a programme of exceptional interest for the instruction and entertainment of the Institution. Papers have already been promised by M. Émil Bertin, Director of the French Government School of Naval Architecture, and M. V. Daymard. There will also be papers by Sir William White, Mr. B. Martell, Dr. Francis Elgar, Mr. Archibald Denny, and Mr. Mark Robinson.

During the Easter vacation the following naturalists have been at work in the Liverpool Marine Biological Station at Port Erin :—Dr. H. O. Forbes, Mr. F. G. Baily, Mr. P. M. C. Kermode, Dr. J. D. Gilchrist (Edinburgh University), Mr. A. O. Walker, Prof. Herdman, and Mr. J. C. Sumner (curator). Two steamer dredging expeditions have been carried out to the west and south of the Isle of Man. On these a small shank trawl was worked, in addition to the dredge, with considerable advantage on one occasion, in fact, coming up so full that the net burst with the weight on leaving the water, and the contents were lost. A number of fine Echinoderms were obtained with the trawl, including *Luidea*, *Palmipes*, *Porania*, *Stichaster*, *Synapta*, and other Holothurians. Amongst the Crustacea were *Scalpellum*, *Munida bamffica*, *Xantho tuberculata*, *Ebalia tuberosa* and *E. tumefacta*, *Anapagurus hyndmanni*, *Galathea dispersa* with *Pleurocrypta dispersæ*, *Melphidipella macera*, and a number of the rare shrimp *Pontophilus spinosus*, Leach. Floating fish eggs (plaice and another species) were caught in the tow-nets in Port Erin Bay, both in March and April ; and *Aplysia*, *Doris*, *Sepiola*, and other Invertebrates have spawned in the tanks at the Biological Station. The Liverpool Committee is at present considering the possibility of a further extension of the Station in the form of a hatchery and a large tidal pond, such as was contemplated in Prof. Herdman's original scheme of the institution.

An Italian Seismological Society has recently been founded by Prof. Tacchini, the well-known Director of the Central Meteorological and Geodynamic Office at Rome. Its objects are to make known as soon as possible all the seismic and volcanic phenomena occurring either in Italy or in other countries, to publish short notes about them, descriptions of seismic apparatus, &c., and generally to promote the study of geodynamics. The subscription being moderate, and national and foreign members being admitted on nearly the same terms, the new society, it to be hoped, may become practically a European one.

A useful innovation, that we hope is to be continued, has been started by the Geological Society of London, in the publication of a catalogue of geological literature added to the Society's library during the half-year ended December 1894. This is equivalent to a list of all important books and papers on geology published in that period. Every paper is catalogued separately, under the author's name, and there is a subject-index. The whole is a distinct improvement on the list hitherto published annually in the November *Quarterly Journal* ; and in spite of the improvements, this list for the half-year is less than half the bulk of the last annual one. The only important omission is that of maps. The work will be most useful to all geologists who wish to keep abreast of recently published works.

The science of oscillations has been enriched by some simple and instructive elementary experiments, due to Dr. H. J. Oosting, which are described in the *Zeitschrift für den Physikalischen Unterricht*. That the velocity of a pendulum is greatest when the bob reaches its mean position is shown by means of a pendulum with a mirror attached to it at its axis of suspension, the upper end of the pendulum-rod being attached to a stout wire bridge, the feet of which take the place of the knife edge. When a beam of light is reflected from this mirror, a line of light is formed upon the screen if the pendulum vibrates rapidly enough. The light from the lamp is made intermittent by a uniformly revolving disc provided with holes bored at equal intervals near the edge. A series of points are then produced on the screen, which are crowded together towards the ends, and further apart towards the middle of the line of light, the distance being proportioned to the velocity of the bob.

Another neat contrivance designed by the Dutch physicist is one for producing Lissajou's curves resulting from the combination of two vibrations at right angles to each other. The simplest form of vibrating mirrors consists of two small mirrors attached to wires stretched in a vertical and horizontal position respectively. The periods of vibration are adjusted by screws carrying nuts mounted behind the mirror at right angles to the wire. The vibration is made slower by screwing the nuts outwards ; or, if a pendulum is to be used, it is attached to the bottom of a U-shaped wire bent out and down at the upper ends, so as to oscillate about the ends of the wire. A horizontal circle is attached to the U at the centre of suspension, carrying a precisely similar suspension for a second and smaller pendulum, except that a horizontal mirror takes the place of the horizontal circle. The periods are adjusted by weights movable along the rods, and the resulting curves may be thrown upon the ceiling, or back upon a screen just in front of the lantern with a hole for letting the light through. In this case the beam must be twice reflected from a mirror at 45° to the horizon.

Within the last year or two, the number of methods for observing the characteristics of an alternating current which have been described is considerable. The latest step in this direction is due to M. J. Pionchon (*Comptes rendus*, April 22, 1895), who uses an optical method. The alternating current is passed through a coil, surrounding a tube filled with carbon bisulphide or a saturated solution of mercuric and potassium iodides. This tube is placed between the polariser and analyser of a half-shadow polarimeter. Under these circumstances the plane of polarisation of the light, after its passage through the tube, passes in succession through all the positions between two limits, one of which corresponds to the maximum current in one direction, and the other to the maximum current in the opposite direction.

If, as is the case in practice, the alternations are fairly rapid, the appearance presented is that during the passage of the current the two halves of the field appear equally bright when the analyser is adjusted in the zero position for no current passing. By adopting the stroboscopic method of observation, the author has, however, succeeded in making clear the different phases of illumination through which the field of view passes. By suitably adjusting the difference (ϵ) between the period (T') of the stroboscope and the period (T) of the current, it is possible to see the various phases of the phenomenon pass as slowly as is desirable, the period of the apparent change being to the period of the current in the ratio of T' to ϵ. Hence, by determining the time taken to go through a whole cycle of the apparent changes, the period of the current can be deduced. The maximum value of the current can also be determined. If we denote by μ the rotation of the plane of polarisation of the light corresponding to the maximum current, then, when the principal plane of the analyser is rotated through a less angle than μ, the two halves of the field will appear equally bright twice during each cycle of the apparent changes. If the angle of rotation of the analyser is μ, this equality will only occur once in a cycle, while if the rotation is greater than μ, at no time will the two halves of the field of view appear equally bright. Thus it is quite easy to determine the position of the analyser corresponding to the maximum current. The method also admits of obtaining the current curve, by noting the times at which, when the angle of rotation of the analyser (α) is less than μ, the two halves of the field are equally bright. The current corresponding to the two times observed can be calculated from the value if α, the known dimensions of the coil, and Verdet's constant for the liquid employed.

Prof. Frank Clowes' "Treatise on Practical Chemistry and Qualitative Analysis," adapted for use in the laboratories of colleges and schools, has reached a sixth edition. Messrs. J. and A. Churchill are the publishers of the book.

The *Quarterly Journal* of the Geological Society, just issued (No. 202), contains, in addition to papers read at the meetings, the report of the proceedings of the annual meeting and the anniversary address of the president, Dr. Henry Woodward, on "Some Points in the Life-history of the Crustacea in Early Palæozoic Times."

The very useful pamphlet entitled "Notes on Polarised Light," by Mr. A. E. Munby, which we favourably noticed when it appeared about a year ago, has been translated into Russian by Prof. Glinka, of St. Petersburg University. Students of mineralogy beginning work with the polariscope, will find the contents of the pamphlet of great assistance.

We have received a report of the proceedings of the conference on inland navigation, held in Birmingham in February, by the Federated Institution of Mining Engineers. The report contains some useful information on the important subject of the inland navigation of Great Britain, and a number of valuable suggestions for improving the present inefficient state of our inland waterways.

Messrs. Dulau and Co. have prepared and published a useful catalogue of separate papers from the *Philosophical Transactions* of the Royal Society offered for sale by them. The papers are indexed according to the authors' names. Two other new catalogues which scientific bibliographers will find valuable are R. Friedländer and Son's "Bücher-verzeichniss" (No. 417), containing titles of entomological works, and a list of books issued by Mr. Bernard Quaritch, Piccadilly, S.W.

Science Gossip for May contains several articles of scientific interest. Dr. Dallinger has a note on *Melicerta ringens*, illustrated by drawings of this small though interesting denizen of our ponds. Messrs. Wanklyn and Cooper write on Argon. Mr. Thomas Leighton has an article on "Geology of the Isle of Wight"; and Dr. Guppy writes on "Stations of Plants and Buoyancy of Seeds." Mr. Rudolph Beer has an interesting illustrated article on "Leguminous Plants."

The West Australian Year-Book for 1893–94, issued by the Registrar-General, contains tables showing the results of meteorological observations at the chief observing stations, together with some general remarks on the climate of the colony. The climate varies a good deal in the different parts; in the south and south-west it is excellent, being temperate and cool, with regular and sufficient rainfall. To the eastward the climate is dryer, but little accurate information is available in that direction.

The Report of the Royal Zoological Society of Ireland for the year 1894, shows that the Society is in an exceedingly prosperous condition. Nine lion cubs were born during the year, four of which died, but the five others (all males) were disposed of as exchanges. There are still two lions and five lionesses in the gardens of the Society. The Council has decided to make a donation to the funds of the *Irish Naturalist*, a monthly journal which frequently contains valuable information on the natural history of Ireland.

We have received No. 2 of the Official Guide to the Museums of Economic Botany at the Royal Gardens, Kew, comprising Monocotyledons and Cryptogams. Among the specimens and products belonging to Monocotyledons, by far the larger number are naturally derived from the great order of palms; though the origin is also illustrated of other very important products, such as vanilla, ginger, grains of paradise, arrowroot, the pine-apple, aloes, bananas, the yam, New Zealand hemp, dragon's-blood, and many others. The palms include nearly 100 distinct exhibits, and the grasses upwards of 60. Among Cryptogams, several officinal and other useful articles are obtained from the fibres; while the Algæ and Fungi also yield their quota. A very copious index adds greatly to the value of this publication.

A report, lately issued, on the progress and development of the Manchester Museum, Owens College, during the past four years, shows that the museum is a great power for good. By means of short courses of popular lectures, and informal demonstrations and addresses, the collections have been rendered more interesting and intelligible to the public. Clubs, societies, and classes have paid frequent visits of inspection, and have had the contents of various sections of the museum explained to them by Prof. Boyd Dawkins, or by members of the museum staff. A number of additions have been made in the geological department, one of the most interesting accessions being a model of a glacier, made to scale by Prof. Heim. The zoological and botanical collections have also been benefited by additions, and the specimens in most of the sections have been reduced to law and order.

A recent redetermination of the atomic weight of strontium, by T. W. Richards, confirms the value 87·70 found by Pelouze in 1845. Pelouze employed the method founded on a comparison of anhydrous strontium chloride and silver. The present author finds (1) the ratio between very carefully purified anhydrous strontium bromide and silver in three sets of analyses carried out by different methods, and (2) the ratio $2AgBr : SrBr_2$ in two other series of experiments. Taking oxygen = 16·000, the values obtained for the atomic weight of strontium are respectively (1) 87·644; 87·663; 87·668, and (2) 87·660; 87·650. The mean value from these results may be taken as 87·66.

The additions to the Zoological Society's Gardens during the past week include a Common Squirrel (*Sciurus vulgaris*),

British, presented by Mrs. Herbert Morris; four Yellow-bellied Liothrix (*Liothrix lutens*) from China, presented by Mr. Albert Kettich; a Black-billed Sheathbill (*Chionis minor*), captured at sea, a Water Rail (*Rallus aquaticus*), British, presented by Mr. John Gunn; a Lineolated Parrakeet (*Bolborhynchus lineolatus*) from Mexico, presented by Mr. Edward Hawkins; a Puff Adder (*Vipera arietans*) from South Africa, presented by Mr. J. E. Matcham; a Lear's Macaw (*Ara leari*) from South America, four White-backed Pigeons (*Columba leuconota*) from the Himalayas, a Rock-hopper Penguin (*Eudyptes chrysocome*) from New Zealand, deposited; two Alpine Choughs (*Pyrrhocorax alpinus*), European, purchased; an English Wild Cow (*Bos taurus*, var.), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Relative Densities of Terrestrial Planets.—Attention is drawn to an interesting relation between the diameters and densities of the terrestrial planets, by E. S. Wheeler (*Science*, April 19). The planets are plotted with their diameters in miles as abscissæ, and their densities (the earth being taken as unity) as ordinates, and it is then seen that the points located in this way lie approximately in a straight line. Such a line passes within the limits of the probable errors of all except Venus. If this relation should prove to represent a natural law, the mass of a planet or satellite could be determined from its diameter. Venus is the only one of the five planets (the moon being included) that is any more discrepant than might be expected from its probable error; to make it accordant, either its mass must be increased by one-tenth, or its diameter decreased by one-thirtieth. A sufficient increase in the mass of Venus is stated to be all that is necessary to explain the movement of the perihelion point of the orbit of Mercury; but some of the irregularities of Mercury may be accounted for by the small mass which it is now supposed to have, namely, one-thirtieth that of the earth. In plotting the planetary curve, the density of Mercury adopted, is that derived by Backlund from a discussion of the movements of Encke's comet.

The Orbit of Comet 1893 IV (Brooks).—An investigation of the path of this comet, by Signor Peyra, seems to suggest that it is one of a series travelling in the same elliptic orbit (*Ast. Nach.* No. 3281). This conclusion is based on the similarity of the orbit with those of comets 1864 I and 1822 I, the periods of the comets rendering actual identity impossible. The elements of the orbit are as follows:

T = 1893 Sept. 19·25954 Berlin M.T.

Longitude of perihelion	162° 22′ 19″	1893

The Spectrum of Mars.—A very practical contribution to the recent discussion as to the spectroscopic indications of aqueous vapour in the atmosphere of Mars is afforded by the investigations of Mr. Jewell as to the amount of vapour necessary to produce effects which can be observed with instruments of specified power. (*Astrophysical Journal*, April.) Expressing the amount of vapour present in the air of Baltimore by the depth in inches of a layer of water, the observed monthly mean for January is 0·73, June 3·25, October 1·56, the maximum occurring in June. He concludes that "unless the amount of water in the atmosphere of Mars is greater than that in the earth's atmosphere in October at Baltimore, it is useless to look for the presence of water vapour in the spectrum of Mars, unless our instrumental means are much superior to any hitherto used for that purpose." Since instruments of greater dispersion are unsuitable, because of the lack of sufficient light, there seems but little chance of obtaining any very decisive direct evidence of the presence of water vapour in Mars. It will be remembered that Dr. Janssen and others satisfied themselves as to the indications of water vapour bands in the spectrum of Mars, whilst Prof. Campbell has more recently failed to detect them.

The chances of detecting the presence of oxygen, however, if present, do not seem so hopeless, as the B group is readily seen with small dispersion.

It is also suggested by Mr. Jewell that attempts should be made to observe the chlorophyll bands in the spectrum of the green areas of the planets, since one of the bands is quite strong in the vegetation spectrum.

The Astronomical Society of France.—During the eight years of its existence, this Society has attained a membership of nearly 1000. At the annual meeting held recently, Dr. Janssen was elected president, and M. Camille Flammarion general secretary for the current session. The progress of astronomy in 1894 formed the subject of an address by M. Tisserand, the Director of the Paris Observatory. Among other matters he referred to the reappearance of De Vico's comet (Nature, vol. li. p. 542), which he regarded as further evidence of the fact that, at certain epochs, comets are subject to increases of brightness which they are incapable of maintaining, the increased activity being probably due to internal disturbances, the nature of which are not yet understood. It will be remembered, however, that Mr. Lockyer explains these fluctuations in brilliancy by collisions with meteor-swarms lying in the track of the comet. Referring to minor planets, M. Tisserand believed it not improbable that those appearing as bright as 12th magnitude stars have an average diameter of about 130 kilometres; that is, about one-hundredth of the earth's diameter; at that rate, even a thousand of them would not have a total mass equal to a thousandth part that of the earth, assuming that their mean density is not greater than that of the earth. (*Bull. Mens. Soc. Ast. de France*, May.)

THE ROYAL SOCIETY CONVERSAZIONE.

THE annual Royal Society conversazione, to which gentlemen only are invited, was held in the Society's rooms on Wednesday of last week.

Many branches of science were represented in the exhibits, either by apparatus or by results of research. An exhibit that attracted much attention was the electrical furnace as used for the melting of chromium, titanium, platinum, and other metals, with high melting-points, shown by Prof. Roberts-Austen, C.B. The furnace consisted of a fire-clay case lined with magnesia, and contained a magnesia crucible. The carbon poles were horizontal, the arc being deflected by means of a magnet on to the material to be heated. For purposes of exhibition, an image of the molten contents of the furnace was projected, by means of a lens and mirror, on to a screen; the current employed is usually about 60 or 70 amperes at 100 volts.

Some very valuable metals of the platinum group were exhibited by Messrs. Johnson, Matthey, and Co., among them being a platinum nugget, weighing 158 ozs.; palladium ingot, of 1000 ozs.; rhodium ingot, 72 ozs.; osmium, melted and sponge; ruthenium melted by the electric arc; and pure iridium rolled sheet.

A magnet, showing the effects of currents in iron on its magnetisation, was exhibited by Dr. Hopkinson. A large electromagnet had buried in its substance two coils of comparatively small dimensions, one around the centre of the magnet, the other half-way between the centre and the surface. These coils were connected to two galvanometers. On reversing the current round the magnet it was seen that a considerable time elapsed before either galvanometer showed any substantial current, and that the current in the central coil occurred much later than in that at a less depth in the mass of iron.

Prof. J. A. Fleming showed a synchronising alternating current motor and contact maker, for the delineation of the form of alternating current and electromotive force curves, and a form of resistance of small inductance for use with the apparatus.

An instrument for analysing primary and secondary volts and amperes simultaneously was exhibited by Prof. W. M. Hicks.

Mr. R. E. Crompton had on view electrically heated apparatus, showing the method of applying electricity for heating tools and appliances used in trade; also for domestic purposes. Wires of high resistance composed of nickel, steel, or other suitable alloys, were embedded in an insulating enamel, and by it attached to the various articles to be heated. By this means loss of heat was obviated. Connection was made with the circuit by means of safety connectors, in which the contacts were automatically protected. The perfect flexibility of the system was exemplified in the electric oven, which was heated on all sides top, and bottom, and the temperature of which could be regulated

by turning on or off any part, or the whole of the current. Electrically heated hot-plates, flat-irons, and radiators were shown constructed on the same principle. Mr. Crompton also exhibited the latest form of Crompton potentiometer, for ratio measurements (accuracy 1 in 1,000,000), and simple forms of platinum thermometers for use with potentiometer.

A new instrument for testing the quality of iron in regard to magnetic hysteresis was exhibited by Prof. Ewing (Fig. 1). Its special use is to test sheet-iron for transformers and dynamo armatures. A few strips of the iron to be tested are cut to the length of three inches. These are clamped in a carrier, which is then caused to revolve between the poles of a magnet. The magnet is suspended on a knife-edge, and becomes deflected in consequence of the work expended in overcoming the magnetic hysteresis of the sample. The deflection is observed by means of a pointer, and serves as a measure of the hysteresis. The apparatus is so designed as to make the induction nearly the same in all specimens, notwithstanding differences of permeability. This makes its indications strictly a test of hysteresis.

Mr. L. Pyke showed an arrangement by means of which it is possible to obtain a greater efficiency in the reduction of the highly electro-positive metals from aqueous solutions, into and forming an amalgam with a mercury cathode.

A system of electric meters, viz., voltmeters, ammeters, and wattmeters, suitable for either direct or alternating currents, formed Major Holden's exhibit.

Prof. George Forbes exhibited a torsion model of submarine cable. A thread vertically suspended in oil represented the cable; the torsion (E.M.F.) being applied at the top by vanes and a positive or negative air blast (battery). The whole was suspended at the top by a spring (sending condenser); at the bottom was a mirror to reflect spot of light. This was controlled by a magnet (receiving condenser). Fluid friction represented resistance. Twist represented charge. The model gave signals compared with those of a cable 2000 miles long.

Specimens of the deposit or incrustation on the insulators of the electric light mains at St. Pancras, in which metallic sodium

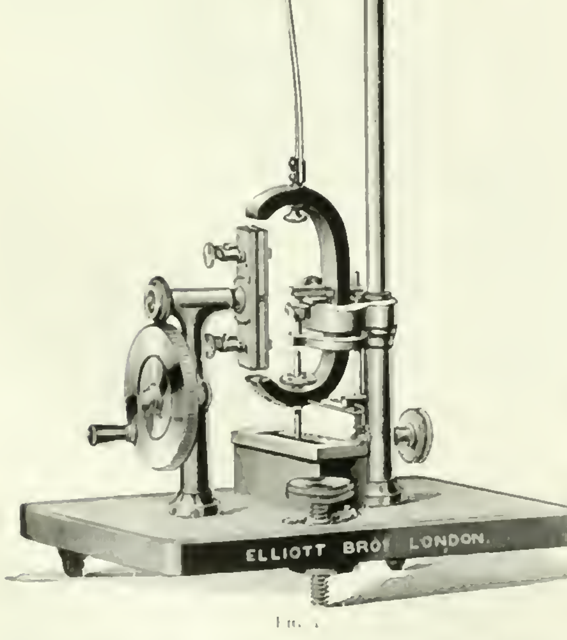

FIG. 1.

and potassium have been found, and of the insulators and wood bearers, which were in use on these mains, were exhibited by Major Cardew, R.E. The deposit was found to have been caused by the passage of alkaline salts in solution to the negative main, the salts being chiefly derived from the neighbouring soil, with which the end fibres of the wood bearers were in contact. Electrolysis of these salts took place with liberation of the metals at the negative main, the metals being oxidised and slowly carbonated in air. During this process nodules of the metal seem to have become embedded in the oxides, and preserved from oxidation.

Mr. Francis Galton showed enlarged finger prints, with descriptive notation, and a print of the hand of a child eighty-six days old.

Prof. J. B. Farmer had on view examples of heterotypical nuclear division in reproductive tissues of plants.

Microscopic specimens illustrating some appearances of nerve-cells were exhibited by Dr. Gustav Mann; and wandering cells of the intestine were shown by Dr. Wesbrook and Mr. W. B. Hardy.

Mr. W. T. Burgess showed the results of experiments in connection with the transmission of infection by flies. Flies having been placed in momentary contact with a cultivation of *Bacillus prodigiosus* (or other suitable chromogenic organism) were allowed to escape into a large room. After some time they were recaptured and caused to walk, for a few seconds, over slices of sterile potatoes, which were then incubated for a few days. The experiments showed that the flies' tracks on the potatoes were marked by vigorous growths of the chromogenic organism, even when the flies spent several hours in constant activity before they were recaptured. The use of pathogenic organisms in these experiments would be attended with obvious dangers, but the results obtained with harmless microbes indicated the constant risks to which flies expose us.

Prof. Gotch and Dr. H. O. Forbes showed a living specimen of the *Malapterurus electricus* from the River Senegal; Mr. Stanley Kent, a new bacterial species; and Mr. D. Sharp, F.R.S., examples of variation in the size of beetles. In some beetles there is great difference in the size of adult individuals of the same species and sex. In one of the cases exhibited—*Brenthus anchorago*—this difference was, in length alone, nearly as five and one. It is believed that these extreme cases occur chiefly in forms in which the males are ornamented with "useless" appendages, *e.g.* the families Scarabæidæ, Lucanidæ, Brenthidæ.

The exhibit of the Marine Biological Association consisted of (1) marine organisms preserved in formic aldehyde, which, in dilute solutions, is specially useful for the preservation of transparent organisms as museum specimens; (2) a new method of fixing methylen-blue preparations. The methylen-blue preparations are fixed with ammonium molybdate. This method, due to Dr. Berthe, of Berlin, has the advantage of retaining the original blue colour of the preparations, and also of allowing the object to be mounted in balsam, or imbedded in paraffin in the usual way; (3) the action of light on the under sides of flat fishes. The flat fishes exhibited were reared in a tank with a flat slate bottom and glass front. Those portions of the under side of a fish which were not in contact with the slate, and to which light was accessible—this point being demonstrated by the exposure of a photographic plate upon which the fish lay—have become pigmented, whilst the remaining portions are without pigment; (4) living representatives of the Plymouth fauna.

A gradient indicator was exhibited by Mr. J. Wimshurst; and Sir Benjamin W. Richardson showed an electrical cabinet, for use in the wards of a hospital.

There were only two astronomical exhibits. Mr. J. Norman Lockyer, C.B., showed an enlargement of a photograph of the spectrum of α Orionis, taken with a 6-inch telescope and an objective prism of 45°.

Mr. Sidney Waters exhibited charts showing the distribution of the nebulæ and star-clusters, and their relation to the Milky Way. These charts, upon which are recorded the position of the 7840 objects of the New General Catalogue of 1888, were designed to show the distribution of the nebulæ and star-clusters, more especially in relation to the Milky Way. The resoluble and irresoluble nebulæ are shown to be most densely scattered in the poles of the galactic circle, and avoid the track of the Milky Way, while the star-clusters follow its course with great fidelity. The evidence derived from this distribution seems to point to some general connection between the nebular system and the system of the stars.

Prof. Ramsay had a spectroscope and Plucker tubes arranged to give ocular demonstration of the spectra of argon extracted from air, and of a mixture of argon and helium extracted from cleveite. It is hardly necessary to say that the spectroscope was in great demand all the evening.

Students' simple apparatus for determining the mechanical equivalent of heat was exhibited by Prof. Ayrton. The apparatus enables the heat equivalent of a watt-second to be experimentally ascertained with an error of less than 1 per cent., without any allowance having to be made for heat lost by conduction, convection, or radiation. It will give the result when 2000 c.c. of water are warmed for two minutes with a current of about 30 amperes, at a pressure of about 10 volts. The conductor consisted of 10 feet of manganin rolled into a thin strip to give off heat rapidly, and formed into a double grid so as to be used as an efficient water stirrer. The cross section of the flexible leads was such that practically no flow of heat occurred between them and the grid when a current of about 30 amperes is used.

Photographs of sections of gold nuggets etched to show crystalline structure, were exhibited by Prof. A. Liversidge. Gold nuggets, on being cut through or sliced and polished, and etched by chlorine water, were found to exhibit well-marked crystalline structure, closely resembling the Widmanstatt figures shown by most metallic meteorites, except that, in the nuggets, the crystals are more or less square in section, and show faces which evidently belong to the octahedron and cube.

Phenomena associated with the formation of cloud were experimentally illustrated by Mr. W. N. Shaw. Clouds formed by mixture of two currents of air of different temperatures were shown in a large glass globe. The currents were due to convection. The motion of the clouds, gave an indication of the motion of the air. Under suitable conditions the motion assumed a gyratory or "cyclonic" character. A second globe was arranged to show the formation of a cloud by the dynamical cooling of air, consequent upon a sudden expansion equivalent to an elevation of about 10,000 feet. The water globules could be seen to fall slowly. A light was arranged at the back of the globe to show (under favourable circumstances) coloured coronæ surrounding a central bright spot. Two other globes were used in conjunction to demonstrate the modification which cloud formation introduces into the dynamical cooling of air. In one of the pair condensation diminished the fall of temperature incidental to sudden expansion, and the difference was indicated by the final pressure-difference between the globes.

There were two barometric exhibits, one a mechanical device for performing temperature corrections in barometers, by Dr. John Shields, and a new form of barometer, exhibited by Dr. J. Norman Collie.

The preparation of acetylene from calcic carbide was shown by Prof. V. B. Lewes. The combustion of acetylene for illuminating purposes attracted great attention. Calcic carbide, formed by the action of carbon on lime at the temperature of the electric furnace, was decomposed by water with evolution of acetylene. The remarkable brilliancy of the flame produced may be judged by the fact that the acetylene when consumed in suitable burners develops an illuminating value of 240 candles per 5 cubic feet of gas.

Generalised frequency curves were exhibited by the Applied Mathematics Department of University College, London, and also compound frequency curves, a harmonic analyser, and a bi-projector.

Mr. T. Clarkson showed his circlographs for drawing and measuring circular curves of any large radius without requiring the centre, with examples of curves. The construction of these instruments is based upon a recent discovery that it is possible to cut a flat plate of steel (of uniform thickness and temper) into a certain form, which imparts to it the property of bending always into circular curves.

Mr. R. Inwards had on view examples of curious mortise joints in carpentry, all made without compression or veneering, and Mr. Hermann Kühne exhibited Junkers' patent calorimeter.

The radial cursor, a new addition to the slide rule, was shown by Mr. F. W. Lanchester. This cursor added to the slide rule makes the rule applicable at once to the calculation of whole or fractional powers, and renders it specially useful for the solution of problems in thermodynamics.

The Cambridge Scientific Instrument Company showed a new form of rocking microtome and a new form of spectrometer, and an improved form of Donkin's harmonograph. This was a modification of Donkin's harmonograph, and draws, on a moving strip of paper, a curve compounded of two simple harmonic motions.

During the evening demonstrations by means of the electric lantern took place in the meeting room.

Prof. A. C. Haddon showed lantern slides illustrating the ethnography of British New Guinea. The slides illustrated the physical characters of different tribes inhabiting British New Guinea, some of the occupations of the people, several kinds of dances, and the distribution of dance-masks. Evidence was given in support of the view that British New Guinea is inhabited by true dark Papuans, and by two distinct lighter Melanesian peoples, one of whom may have come from the New Hebrides, and the other from the Solomon Islands.

Lord Armstrong showed some of the results of his recent experiments on the electric discharge in air. The figures exhibited by means of the lantern, showed various phases, hitherto unobserved, of the brush discharge accompanying the electric spark. They showed also the remarkable modifying effect of induction on the results obtained. The luminous effects were delineated by instantaneous photography, and the mechanical effects by the electric action on dust plates. The spark itself had to be taken in a dark box on a shunt line, as its strong light and violent action would otherwise have been incompatible with the photographic and mechanical methods used in the experiments; but nearly the same tensions were obtained outside the box as within.

THE RARER METALS AND THEIR ALLOYS.[1]

II.

NOW turn to more complex curves taken on one plate by making the sensitised photographic plate seize the critical part of the curve, the range of the swing of the mirror from hot to cold being some sixty feet. The upper curve (Fig. 4) gives the freezing point of bismuth, and you see that surfusion, *a*, is clearly marked, the temperature at which bismuth freezes being 268°. The lower point represents the freezing point of tin, which we know is 231° C., and in it surfusion, *b*, is also clearly marked. The lowest curve of all contains a subordinate point in the cooling curve of standard gold, and this subordinate point, *c*, which you will observe is lower than the freezing point of tin, is caused by the falling out of solution of a small portion of bismuth, which

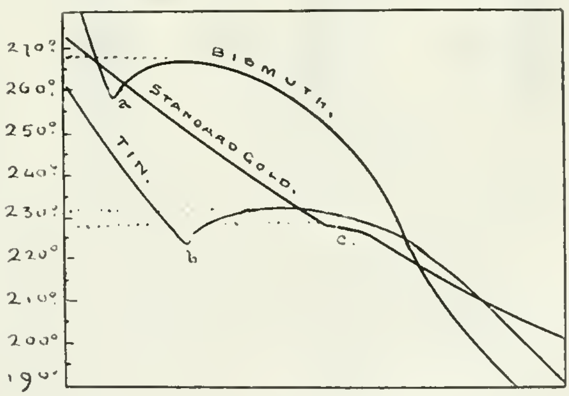

Fig. 4.

alloyed itself with some gold atoms, and "fell out" below the freezing point not only of bismuth itself but of tin. Now gold with a low freezing point in it like this is found to be very brittle, and we are in a fair way to answer the question why $\frac{2}{10}$ per cent of zirconium doubles the strength of gold, while $\frac{2}{10}$ per cent of thallium, another rare metal, halves the strength. In the case of the zirconium the subordinate point is very high up, while in the case of the thallium it is very low down. So far as my experiments have as yet been carried, this seems to be a fact which underlies the whole question of the strength of metals and alloys. If the subordinate point is low, the metal will be weak; if it is high in relation to the main setting point, then the metal will be strong, and the conclusion of the whole matter is this. The rarer metals which demand for their isolation from their oxides either the use of aluminium or the electric arc, never, so far as I can ascertain, produce low freezing points when they are added in small quantities to those metals which are used for constructive purposes. The difficultly fusible rarer metals are never the cause

[1] A Friday evening discourse, delivered at the Royal Institution on March 15, by Prof. Roberts-Austen, C.B., F.R.S. (Continued from p. 18.)

of weakness, but always confer some property which is precious in industrial use. How these rarer metals act, why the small quantities of the added rare metals permeate the molecules, or, it may be the atoms, and strengthen the metallic mass, we do not know; we are only gradually accumulating evidence which is afforded by this very delicate physiological method of investigation.

As regards the actual temperatures represented by points on such curves, it will be remembered that the indications afforded by the recording pyrometer are only relative, and that gold is one of the most suitable metals for enabling a high, fixed point to be determined. There is much trustworthy evidence in favour of the adoption of 1045° as the melting point hitherto accepted for gold. The results of recent work indicate, however, that this is too low, and it may prove to be as high as 1061·7, which is the melting point given by Heycock and Neville[1] in the latest of their admirable series of investigations to which reference was made in my Friday evening lecture of 1891.

It may be well to point to a few instances in which the industrial use of such of the rarer metals, as have been available in sufficient quantity, is made evident. Modern developments in armour-plate and projectiles will occur to many of us at once. This diagram (Fig 5) affords a rapid view of the progress which has been made, and in collecting the materials for it from various sources, I have been aided by Mr. Jenkins. The effect of projectiles of approximately the same weight, when fired with the same velocity against six-inch plates, enables comparative results to be studied, and illustrates the fact that the rivalry between artillerists who design guns, and metallurgists who attempt to produce both impenetrable armour-plates and irresistible projectiles, forms one of the most interesting pages in our national history. When metallic armour was first applied to the sides of war vessels, it was of wrought iron, and proved to be of very great service by absolutely preventing the passage of ordinary cast-iron shot into the interior of the vessel, as was demonstrated during the American Civil War in 1866. It was found to be necessary, in order to pierce the plates, to employ harder and larger projectiles than those then in use, and the chilled cast iron shot with which Colonel Palliser's name is identified proved to be formidable and effective. The point of such a projectile was sufficiently hard to retain its form under impact with the plate, and it was only necessary to impart a moderate velocity to a shot to enable it to pass through the wrought-iron armour (A, Fig. 5).

It soon became evident that in order to resist the attack of such projectiles with a plate of any reasonable thickness, it would be necessary to make the plate harder, so that the point of the projectile should be damaged at the moment of first contact, and the reaction to the blow distributed over a considerable area of the plate. This object could be attained by either using a steel plate in a more or less hardened condition, or by employing a plate with a very hard face of steel, and a less hard but tougher back. The authorities in this country during the decade, 1880–90, had a very high opinion of plates that resisted attack without the development of through-cracks, and this led to the production of the compound plate. The backs of these plates (B, Fig. 5) are of wrought iron, the fronts are of a more or less hard variety of steel, either cast on, or welded on by a layer of steel of an intermediate quality cast between the two plates. Armour-plates of this kind differ in detail, but the principle of their construction is now generally accepted as correct.

Such plates shown by plate B, resisted the attack of large Palliser shells admirably, as when such shells struck the plate they were damaged at their points, and the remainder of the shell was unable to perforate the armour against which it was directed. An increase in the size of the projectiles led, however, to a decrease in the resisting power of the plates, portions of the hard face of which would at times be detached in flakes from the junction of the steel and the iron. An increase in the toughness of the projectiles by a substitution of forged chrome-steel for chilled iron (see lower part of plate B), secured a victory for the shot, which was then enabled to impart its energy to the plate faster than the surface of the plate itself could transmit the energy to the back. The result was that the plate was overcome, as it were, piecemeal; the steel surface was not sufficient to resist the blow itself, and was shattered, leaving the projectile an easy victory over the soft back. The lower part of plate, B (in Fig. 5), represents a similar plate to that used in the *Nettle* trials of 1888.[1] It must not be forgotten in this connection, that the armour of a ship is but little likely to be struck twice by heavy projectiles in the same place, although it might be by smaller ones.

Plates made entirely of steel, on the other hand, were found, prior to 1888, to have a considerable tendency to break up completely when struck by the shot. It was not possible, on that account, to make their faces as hard as those of compound plates; but while they did not resist the Palliser shot nearly so well as the rival compound plate, they offered more effective resistance to steel shot (see lower part of plate C, Fig. 5).

It appears that Berthier recognised, in 1820, the great value of chromium when alloyed with iron; but its use for projectiles, although now general, is of comparatively recent date, and these projectiles now commonly contain from 1·2 to 1·5 per cent. of chromium, and will hold together even when they strike steel plates at a velocity of 2000 feet per second,[2] (see lower part of plate D); and unless the armour-plate is of considerable thickness, such projectiles will even carry bursting charges of explosives through it. [The behaviour of a chromium-steel shell, made by Mr. Hadfield, was dwelt upon, and the shell was exhibited.]

It now remained to be seen what could be done in the way of toughening and hardening the plates so as to resist the chrome steel shot. About the year 1888, very great improvements were made in the production of steel plates. Devices for hardening and tempering plates were ultimately obtained, so that the latter were hard enough throughout their substance to give them the necessary resisting power without such serious cracking as had occurred in previous ones. But in 1889, Mr. Riley exhibited, at the meeting of the Iron and Steel Institute, a thin plate that owed its remarkable toughness to the presence of nickel in the steel. The immediate result of this was that plates could be made to contain more carbon, and hence be harder, without at the same time having increased brittleness; such plates, indeed, could be water hardened and yet not crack.

ATTACK OF 6-INCH ARMOUR-PLATES BY 4·72-INCH SHELLS, WEIGHING 57·2 LBS.

A	B	C	D	E	F
Wrought iron. 1888.	Compound plate. 1888.	Steel. 1888.	Steel. 1894.	Nickel-steel. 1894.	Harveyed, nickel-steel. 1894.

FIG. 5. The upper series of projectiles are Palliser chilled-iron shells, and the lower are chrome-steel. In each case the velocity of the projectile is approximately 1640 foot-seconds, and the energy 1070 foot-tons.

[1] Trans. Chem. Soc., vol. lxvii., 1895, p. 160.

[1] *Proceedings* Institution of Civil Engineers, 1889, vol. xcviii. p. 1, *et seq.*
[2] *Journal* U.S. Artillery, 1894. Vol. [illegible], p. 197

The plate E (Fig. 5) represents the behaviour of nickel-steel armour. It will be seen that it is penetrated to a much less extent than in the former case; at the same time there is entire absence of cracking.

Now as to the hardening processes. Evrard had developed the use of the lead bath in France, while Captain Tressider[1] had perfected the use of the water-jet in England for the purpose of rapidly cooling the heated plates. The principle adopted in the design of the compound plates has been again utilised by Harvey, who places the soft steel or nickel-steel plate in a furnace of suitable construction, and covers it with carbonaceous material such as charcoal, and strongly heats it for a period, which may be as long as 120 hours. This is the old Sheffield process of cementation, and the result is to increase the carbon from 0·35 per cent. in the body of the plate to 0·6 per cent., or even more at the front surface, the increase in the amount of carbon only extending to a depth of two or three inches in the thickest armour.

The carburised face is then "chill-hardened," the result being that the best chrome-steel shot are shattered at the moment of impact, unless they are of very large size as compared with the thickness of the plate. The interesting result was observed lately[2] of shot doing less harm to the plate, and penetrating less, when its velocity was increased beyond a certain value, a result due to a superiority in the power of the face of the plate to transmit energy over that possessed by the projectile, which was itself damaged, when a certain rate was exceeded. At a comparatively low velocity the point of the shot would resist fracture, but the energy of the projectile is not then sufficient to perforate the plate, which would need the attack of a much larger gun firing a projectile at a lower velocity.

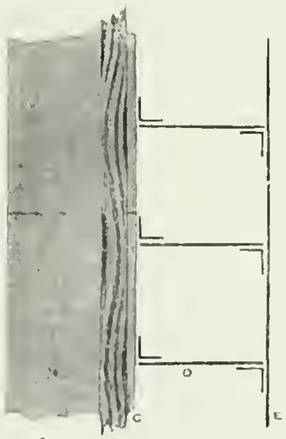

FIG. 6.—Section of Barbette of the *Majestic*.

The tendency to-day is to dispense with nickel, and to use ordinary steel, "Harveyed;"[3] this gives excellent six-inch plates, but there is some difference of opinion as to whether it is advantageous to omit nickel in the case of very thick plates, and the problem is now being worked out by the method of trial. Probably, too, the Harveyed plates will be much improved by judicious forging after the process, as is indicated by some recent work done in America. The use of chromium in the plates may lead to interesting results.

Turn for a moment to the "*Majestic*" class of ships, the construction of which we owe to the genius of Sir William White, to whom I am indebted for a section representing the exact size of the protection afforded to the barbette of the *Majestic*. [This section was exhibited and is shown as reduced to the diagram Fig. 6.] Her armour is of the Harveyed steel, which has hitherto proved singularly resisting to chromium projectiles.

In this section, A represents a 14-inch Harveyed steel armour-plate; B, a 4-inch teak backing; C, a 1½-inch steel plate; D, ½-inch steel frames; and E, ½-inch steel linings.

It will, I trust, have been evident that two of the rarer metals, chromium and nickel, are playing a very important part in our national defences; and if I ever lecture to you again, it may be possible for me to record similar triumphs for molybdenum, titanium, vanadium, and others of these still rarer metals.

Here is another alloy, for which I am indebted to Mr. Hadfield. It is iron alloyed with 25 per cent. of nickel, and Hopkinson has shown that its density is permanently reduced by two per cent. by an exposure to a temperature of −30°, that is the metal expands at this temperature.

Supposing, therefore, that a ship-of-war was built in our climate of ordinary steel, and clad with some three thousand tons of such nickel-steel armour, we are confronted with the extraordinary fact that if such a ship visited the Arctic regions, it would actually become some two feet longer, and the shearing which would result from the expansion of the armour by exposure to cold would destroy the ship. Before I leave the question of the nickel-iron alloys, let me direct your attention to this triple alloy of iron, nickel and cobalt in simple atomic proportions. Dr. Oliver Lodge believes that this alloy will be found to possess very remarkable properties; in fact, as he told me, if nature had properly understood Mendeleef, this alloy would really have been an element. As regards electrical properties of alloys, it is impossible to say what services the rarer metals may not render; and I would remind you that "platinoid," mainly a nickel-copper alloy, owes to the presence of a little tungsten its peculiar property of having a high electrical resistance which does not change with temperature.

One other instance of the kind of influence the rarer metals may be expected to exert is all that time will permit me to give you. It relates to their influence on aluminium itself. You have heard much of the adoption of aluminium in such branches of naval construction as demand lightness and portability. During last autumn Messrs. Yarrow completed a torpedo boat which was built of aluminium alloyed with 6 per cent. of copper. Her hull is 50 per cent. lighter, and she is 3½ knots faster than a similar boat of steel would have been, and, notwithstanding her increased speed, is singularly free from vibration.

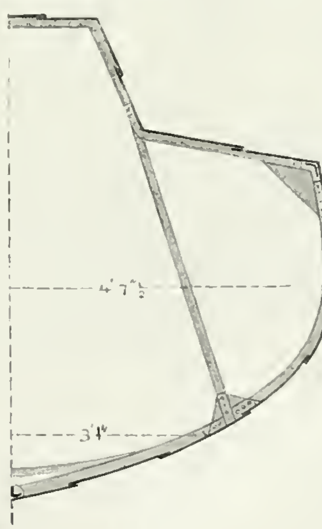

FIG. 7. Half-section Midship of Aluminium Torpedo-boat

Her plates are $\frac{1}{16}$th inch thick, and $\frac{1}{8}$th inch where greater strength is needed. It remains to be seen whether copper is the best metal to alloy with aluminium. Several of the rarer metals have already been tried, and among them titanium. Two per cent. of this rare metal seems to confer remarkable properties on aluminium, and it should do so according to the views I have expressed, for the cooling curve of the titanium-aluminium alloy would certainly show a high subordinate freezing point.

Hitherto I have appealed to industrial work, rather than to abstract science, for illustrations of the services which the rarer metals may render. One reason for this is that at present we have but little knowledge of some of the rarer metals apart from their association with carbon. The metals yielded by treatment

[3] *Engineering*, vol. lvii., 1894, pp. 465, 530, 595.

of oxides in the electric arc are always carbides. There are, in fact, some of the rarer metals which we, as yet, can hardly be said to know except as carbides. As the following experiment is the last of the series, I would express my thanks to my assistant, Mr. Stansfield, for the great care he has bestowed in order to ensure their success. Here is the carbide of calcium which is produced by heating lime and carbon in the electric arc. It possesses great chemical activity, for if it is placed in water the calcium seizes the oxygen of the water, while the carbon also combines with the hydrogen, and acetylene is the result, which burns brilliantly. [Experiment shown.] If the carbide of calcium be placed in chlorine water, evil smelling chloride of carbon is formed.

In studying the relations of the rarer metals to iron, it is impossible to dissociate them from the influence exerted by the simultaneous presence of carbon; but carbon is a protean element—it may be dissolved in iron, or it may exist in iron in any of the varied forms in which we know it when it is free. Matthiessen, the great authority on alloys, actually writes of the "carbon-iron alloys." I do not hesitate therefore, on the ground that the subject might appear to be without the limits of the title of this lecture, to point to one other result which has been achieved by M. Moissan. Here is a fragment of pig iron highly carburised: melt it in the electric arc in the presence of carbon, and cool the molten metal suddenly, preferably by plunging it into molten lead. As cast iron expands on solidification, the little mass will become solid at its surface and will contract; but when, in turn, the still fluid mass in the interior cools, it expands against the solid crust, and consequently solidifies under great pressure. Dissolve such a mass of carburised iron in nitric acid to which chlorate of potash is added; treat the residue with caustic potash, submit it to the prolonged attack of hydrofluoric acid, then to boiling sulphuric acid, and finally fuse it with potash, to remove any traces of carbide of silicon, and you have carbon left, but—in the form of *diamonds*.

If you will not expect to see too much, I will show you some diamonds I have prepared by strictly following the directions of M. Moissan. As he points out, these diamonds, being produced under stress, are not entirely without action on polarised light, and they have, sometimes, the singular property of flying to pieces like Rupert's drops when they are mounted as preparations for the microscope. [The images of many small specimens were projected on the screen from the microscope, and (Fig. 8, E.) shows a sketch of one of these. The largest diamond yet produced by M. Moissan, is 0·5 millimetre in diameter.]

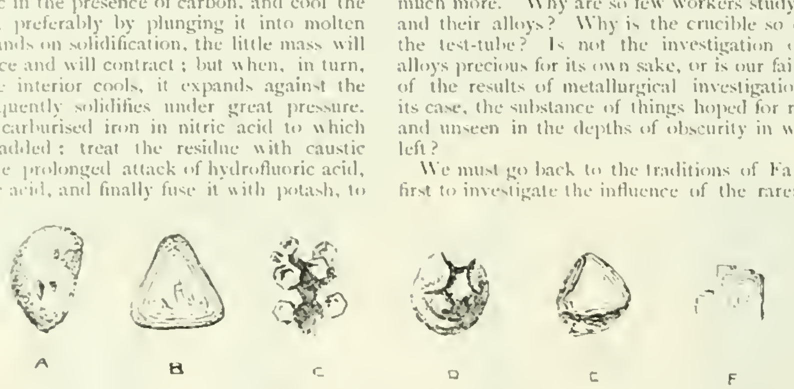

Fig. 8.—Preparations for the microscope of diamonds and other forms of carbon obtained from carburised iron.

A (Fig. 8) represents the rounded, pitted surface of a diamond, and B a crystal of diamond from the series prepared by M. Moissan, drawings of which illustrate his paper.[1] The rest of the specimens, C to F, were obtained by myself by the aid of his method as above described. C represents a dendritic growth apparently composed of hexagonal plates of graphite, while D is a specimen of much interest, as it appears to be a hollow sphere of graphitic carbon, partially crushed in. Such examples are very numerous, and their surfaces are covered with minute round graphitic pits and prominences of great brilliancy. Specimen E (which, as already stated, was one of a series shown to the audience) is a broken crystal, probably a tetrahedron, and is the best crystallised specimen of diamond I have as yet succeeded in preparing. Minute diamonds, similar to A, may be readily produced, and brilliant fragments, with the lamella structure shown in F, are also often met with.

The close association of the rarer metals and carbon and their intimate relations with carbon, when they are hidden with it in iron, enabled me to refer to the production of the diamond, and afford a basis for the few observations I would offer in conclusion. These relate to the singular attitude towards metallurgical research maintained by those who are in a position to promote the advancement of science in this country. Statements respecting the change of shining graphite into brilliant diamond are received with appreciative interest; but, on the other hand, the vast importance of effecting similar molecular changes in metals is ignored.

We may acknowledge that "no nation of modern times has done so much practical work in the world as ourselves, none has applied itself so conspicuously or with such conspicuous success to the indefatigable pursuit of all those branches of human knowledge which give to man his mastery over matter."[1] But it is typical of our peculiar British method of advance to dismiss all metallurgical questions as "industrial," and leave their consideration to private enterprise.

We are, fortunately, to spend, I believe, eighteen millions this year on our Navy, and yet the nation only endows experimental research in all branches of science with four thousand pounds. We rightly and gladly spend a million on the *Magnificent*, and then stand by while manufacturers compete for the privilege of providing her with the armour-plate which is to save her from disablement or destruction. We as a nation are fully holding our own in metallurgical progress, but we might be doing so much more. Why are so few workers studying the rarer metals and their alloys? Why is the crucible so often abandoned for the test-tube? Is not the investigation of the properties of alloys precious for its own sake, or is our faith in the fruitfulness of the results of metallurgical investigation so weak that, in its case, the substance of things hoped for remains unsought for and unseen in the depths of obscurity in which metals are still left?

We must go back to the traditions of Faraday, who was the first to investigate the influence of the rarer metals upon iron, and to prepare the nickel-iron series of which so much has since been heard. He did not despise research which might possibly tend to useful results, but joyously records his satisfaction at the fact that a generous gift from Wollaston of certain of the "scarce and more valuable metals" enabled him to transfer his experiments from the laboratory in Albemarle Street to the works of a manufacturer at Sheffield.

Faraday not only began the research I am pleading for to-night, but he gave us the germ of the dynamo, by the aid of which, as we have seen, the rarer metals may be isolated. If it is a source of national pride that research should be endowed apart from the national expenditure, let us, while remembering our responsibilities, rest in the hope that metallurgy will be well represented in the Laboratory which private munificence is to place side by side with our historic Royal Institution.

ELECTRICITY AND OPTICS.

A MEMOIR of singular interest, and one of which it would be well if the contents could be made more readily accessible to students in this country, has lately been published by Prof. Righi.[2] Among the numerous papers published during the last twenty years by Prof. Righi there are several (on electric discharges, on electric shadows and photo-electric phenomena) which indicate his interest in the relations between light and electricity. Since Hertz succeeded in obtaining rays of electric force, and demonstrated the reflection, refraction and interference of electric radiation, other experimenters have endeavoured to extend and complete the analogy between electromagnetic and luminous vibrations. Thus Lodge and Howard showed that electric radiation could be concentrated by means of large lenses;

[1] *The Times*, February [illegible], 1895.
[2] "Sulle oscillazioni elettriche a piccola lunghezza d'onda e sul loro impiego nella produzione di fenomeni analoghi ai principali fenomeni dell' ottica." (Bologna: 1894).

Boltzmann appears to have performed an experiment similar to Fresnel's with inclined mirrors; Trouton has drawn attention to phenomena similar to those of thin plates; and others have experimented with wire gratings like those by means of which Hertz demonstrated the polarisation of electric radiation: but the great wave-length (about half a metre) of the oscillations used has been a stumbling-block in the way of more delicate experiments. Prof. Righi has succeeded in producing oscillations having a wave-length as small as 2·6 cm., and has devised a novel form of resonator made by taking a strip of silvered glass, dissolving away the varnish from the back, and drawing a diamond-line across. He has thus been able to demonstrate the analogy with other phenomena of optics, among which may be mentioned:—Fresnel's interference-experiments with inclined mirrors and biprism; interference by reflection from thin plates and by transmission through them; diffraction by various means (slits, edges, Fresnel's diaphragm); elliptic and circular polarisation; and total reflection. The description of the experiments is accompanied with full theoretical discussions; and if Prof. Righi does not aim at the general treatment which is suitable to a treatise like Poincaré's, he, at any rate, succeeds admirably in showing how the border-land between electricity and optics is being actually explored.

In another memoir,[1] Prof. Righi develops Hertz's equations so as to find the electromagnetic disturbance produced by the combination of two small rectilinear electric oscillations at right angles, say along the axes of z and y, having equal amplitudes but differing in phase by a quarter wave-length. Each of these might be replaced by the mechanical movement of equal and opposite electric charges, oscillating with pendular motion about the origin along one of the axes. Two such mechanical motions at right angles, differing in phase by a quarter wave-length, would compound into a motion of uniform rotation in a circle about the origin in the plane of zy. The disturbance due to such a circular motion of equal and opposite charges would, with certain limitations, be the same as the disturbance produced by the combination of the two rectilinear oscillations first considered. Prof. Righi shows that it takes the form of a spherical wave having its centre at the origin of coordinates. The vibrations are in general (to use the language of optics) elliptically polarised: in the neighbourhood of the axis of x they are circularly polarised: in the equatorial plane zy they are plane-polarised.

In a third memoir, by Prof. H. A. Lorentz,[2] an attempt is made to establish a theory of electrical and optical phenomena in connection with moving bodies. This naturally involves a discussion of the relation between the ether and ponderable bodies in motion, and of the theories proposed by Fresnel and Stokes respectively. After weighing the evidence on both sides, the Leyden professor is of opinion that Fresnel's conception offers fewer difficulties than its rival. The question is of importance in electricity as well as in optics; it is necessarily raised by a rigid examination of any electrical phenomenon, such as the motion of a charged body or of a conductor carrying a current. Prof. Lorentz bases his explanation of electrical phenomena on the hypothesis that all bodies contain small electrically charged particles, and that all electrical processes depend upon the position and motion of these "ions." This conception of ionic charges is universally accepted for electrolytes, and also forms the most probable explanation of the convective discharge of electricity in gases. It is here extended to ponderable dielectrics, the "polarisation" of which is ascribed to the existence of such particles in positions of equilibrium from which they can only be displaced by external electrical forces. The periodically changing polarisations which, according to Maxwell's theory, constitute light-vibrations, here become vibrations of the ions.

pr.

SCIENCE IN THE MAGAZINES.

A MOST interesting account of Madame Kovalevsky's eventful life is contributed to the *Fortnightly* by Mr. E. W. Carter. The sketch is based upon that gifted mathematician's own published recollections, and Madame Edgren-Leffler's biography of her lamented friend. As there are some who are not familiar with the career of the subject of Mr. Carter's article, a short summary of the chief points may be of interest. Sophie Kovalevsky was born at Moscow about 1850, where the first five years of her life were spent. Her father then removed to Palibino, in the government of Vitebsk. It was there that her bent for mathematics first showed itself. A room had been papered with old disused printing paper, amongst which were several sheets of Ostrogradski's lectures on the differential and integral calculus. "This room possessed a strong fascination for the little seven-year-old maiden. Here she was to be found daily, her attention riveted on these walls, striving to understand something of the strange figures and stranger formulas. 'I remember,' says Madame Kovalevsky, 'that every day I used to spend hours before these mysterious walls, struggling to understand some of the sentences, and to find the order of the sheets. By dint of long contemplation, some of the formulas became firmly fixed in my memory, and even the text, though I could comprehend nothing of it at the time, left its impression on my brain.' When several years later, her father was prevailed on to let her have some instruction in mathematics, the results were a surprise and a revelation to all concerned; not least to the little pupil herself. The mysteries of the walls now grew clear, and her progress was made by leaps and bounds. The differential calculus presented no difficulties to her, and her tutor found that she knew the formulas by heart, and arrived at solutions and explanations quite independent of his aid."

In October, 1868, Sophie Kroukovsky contracted the romantic marriage with Vladimir Kovalevsky, and the two went to Heidelberg as students at the University. After two terms spent at Heidelberg, she moved to Berlin, where she worked for four years under the direction of Prof. Weierstrasse, "the father of modern mathematical analysis." During this period, she was occupied in writing the three important treatises which subsequently gained for her the degree of Doctor in Philosophy at Göttingen. Passing over the next few years in Madame Kovalevsky's life, during which her husband died, we come to the winter of 1883-84, when she went to Stockholm as the "Docent" of Prof. Mittag-Leffler. A course of lectures delivered during the winter session led to her appointment to the chair of higher mathematics at the University of Stockholm, in July, 1884, a post which she occupied until her death. The crowning scientific labour of her life was the treatise which gained for her the Bordin prize of the Paris Academy in 1888. The subject proposed was "To perfect in one important point the theory of the movement of a solid body round an immovable point," and in recognition of the extraordinary merits of Mdme Kovalevsky's work, the judges raised the amount of the prize from three thousand to five thousand francs. But the distinguished authoress did not live many years to enjoy the high position she had gained. In February, 1891, she was attacked by an illness which ended fatally after three or four days. So passed away a woman of magnificent gifts, who, "Taking the direction of her life into her own hands, and choosing for herself one of the steepest paths to fame, she traversed it with swift and steady steps."

Mr. W. H. Hudson contributes to the *Fortnightly* an article on "The Common Crow," a bird which he finds from inquiries, "is no longer to be found as a breeder, or is exceedingly rare, in districts where game is very strictly preserved; but that in the wilder counties where game is not strictly preserved, in wooded hilly places, he still exists in diminished numbers as a breeding species." Another article in the same magazine, on "Danish Butter Making," by Mrs. Alec Tweedie, furnishes instructive reading for British agriculturists.

The remarkable growth of electric railroad mileage in the United States, during the past five years, is brought out in an article by Mr. Joseph Wetzler, in *Scribner*. "At the present time," he says, "there are over eight hundred and fifty electric railways in the United States, operating over 9000 miles of track and 23,000 cars, and representing a capital investment of over four hundred million dollars. What stupendous figures, when we consider that in 1887 the number of such roads amounted to only thirteen, with scarcely one hundred cars!" A quotation from a paper in the series on "The Art of Living," contributed by Mr. Robert Grant to the same magazine, is worth giving here. "There are signs that those in charge of our large educational institutions all over the country are beginning to recognise that ripe scholarship and rare abilities as a teacher are entitled to be well recompensed pecuniarily, and that the breed of such men is likely to increase somewhat in proportion to the size and number of the prizes offered. Our college presidents and

[1] "Sulle onde electromagnetiche generate da duo piccole oscillazioni elettriche ortogonali oppure per mezzo di una rotazione uniforme." (Bologna: 1894).

[2] "Versuch einer Theorie der elektrischen und optischen Erscheinungen in bewegten Körpern." (Leyden: 1895).

professors, those at the head of our large schools and seminaries, should receive such salaries as will enable them to live adequately. By this policy not only would our promising young men be encouraged to pursue learning, but those in the highest places would not be forced by poverty to live in comparative retirement, but could become active social figures and leaders."

Evolution, and problems belonging to it, crop up periodically as subjects of magazine articles. In the *Contemporary*, A. Fogazzaro, "writer of verses and novels," devotes a number of pages to the polemic battles that have been fought over the evolutionary idea, from the time of Lamarck. "For the Beauty of an Ideal" is the title of his article, which mostly aims at showing how the new wine of evolution may be put into old bottles of Catholic doctrine." A paper on "Evolution and Heredity" is contributed by Dr. G. Symes Thompson to the *Humanitarian*. An introduction to a series of articles on "Professional Institutions," by Mr. Herbert Spencer, appears in the *Contemporary*. The articles will, in their eventual form, constitute part vii. of the "Principles of Sociology."

Two papers in the *Century* call for brief notice. In one, Mr. W. E. Smythe shows how parts of the great arid region to the west of the one-hundredth meridian in the United States have been benefited by careful irrigation. "The work of reclamation has been going forward silently, but gradually and surely, for the better part of a generation. Between ten and twenty millions of acres are now under ditch, and some slight rivulets of population have begun to trickle in upon the lands. But the threshold is scarcely passed. The arid region as a whole comprises more than 800,000,000 acres. Of this empire more than half a billion acres is still the property of the Government." The second paper to which reference has been made, is a short description of three reproductions from photographs of the tree beneath which was buried the heart of Dr. Livingstone. The tree was found near the site of the deserted village of Chitambo, on the south shore of Lake Bangweolo. Upon it, Jacob Wainwright, the Nassick boy who read the Burial Service, chiselled the words, still plainly visible, "Dr. Livingstone, May 4, 1873. Jazuza. Mniasere. Vchopere."

The *Reliquary and Illustrated Archæologist* (April) contains an account, by Mr. Miller Christy, of the exploration of "Deneholes" in Essex and Kent, conducted by the Essex Field Club. Deneholes are ancient artificial caverns in the chalk, having deep, narrow, vertical entrances. They are found in various parts of England, but especially along the banks of the Thames, in Essex and Kent. Mr. Christy has explored many of them, and his opinion as to their origin is: "On the whole, the only conclusion which it seems as yet safe to arrive at is that the mystery surrounding the origin of the Deneholes and the purposes of their makers still constitutes one of the most interesting and perplexing problems yet remaining unsolved in British archæology, perhaps we may say in prehistoric British archæology."

Mr. A. Symons Eccles, in the *National*, writes on "Headaches," and, in the course of his paper, gives the opinion of a distinguished neurologist, that almost every man of science of distinction in London suffers from sick-headache, or migraine, on account of excessive intellectual activity. Mr. Eccles says if they "will sit down to dinner in a state of nervous exhaustion, or do brain work directly after taking food, they can hardly hope to escape from an attack of migraine." In the same review, Miss Balfour concludes the account of her journey through the British South Africa Company's territory, in 1894.

A brief notice will suffice for the other articles in the magazines and reviews received by us. A previously unpublished paper of Richard Jefferies' appears in *Longman's Magazine*, and also a poem by the late Dr. G. J. Romanes. In the *English Illustrated*, the articles from which natural knowledge may be gathered are "Mountaineering in Westmoreland," by Mr. J. F. Fraser; "Stalking the Haplocerus in the Selkirks," by Mr. W. A. Baillie-Grohman; and a "Moorland Idyll," by Mr. Grant Allen. In the *Quarterly Review*, the recently published biographies of Buckland and Owen are used as the basis for an article on advances in the science of geology during this century. *Good Words* contains a short illustrated paper on the Dandelion, by Dr. Hugh Macmillan, and one on "The Sea Birds of the Cape," by the Rev. W. Greswell. Another readable article on birds is Mr. C. J. Cornish's "Birds of the Cliff," in the *Sunday Magazine*. *Chambers's Journal* has the usual complement of instructive articles on more or less scientific topics. Finally, the *Westminster Quarterly Review* contains contributions by Dr. W. T. Greener and Sir Henry Howorth.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Term is now in full swing, and the usual courses of lectures are being delivered in the various departments of Natural Science. The changes from last Term's list are, that Sir J. Conroy and Mr. Frederick Smith have returned to Oxford, and are lecturing on Radiation and Mechanics, respectively, at Balliol and Trinity Colleges. In the Physiological Department, Prof. Gotch has begun his duties as Waynflete Professor, and is lecturing on Mondays and Tuesdays on the Physiology of the Central Nervous System.

Mr. H. Balfour, Curator of the Pitt-Rivers Museum, has been seriously ill, and is absent from Oxford for this Term, being obliged to go abroad for the sake of his health.

In a Congregation, held on Tuesday, May 7, the proposed Statute on Research Degrees was again under discussion, having reached what is technically known as the twelve-member amendment stage. The House reaffirmed by the narrow majority of 39 against 37, the clause which was passed by a large majority last Term, which states that Science shall be held to include Mathematics, Natural Science, Mental and Moral Science. Other clauses, mostly of consequential importance, were added or rejected, amongst them being one of some importance to intending Candidates, which allows residence in the Vacation to count towards the residence of eight terms required by the Statute.

In the same Congregation, Dr. E. B. Tylor, Reader in Anthropology, was constituted Professor in Anthropology during the tenure of his office as Reader in Anthropology.

The seventh summer meeting of University Extension and other Students will be held this year in Oxford. The meeting, as in previous years, will be divided into two parts: the first part will last from Thursday evening, August 1, to August 12, the second from August 12 to August 26. There will be lectures during both parts of the meeting on Natural Science, with classes for practical work. Among the lecturers will be Prof. Green, Prof. Odling, Dr. Kimmins, Dr. Fison, Mr. Carus-Wilson, Mr. J. E. Marsh, Mr. P. Groom, Dr. Wade, and Mr. G. C. Bourne.

The fourth "Robert Boyle" lecture of the Oxford University Junior Scientific Club will be delivered by Prof. Crum-Brown, F.R.S., on Monday next. His subject will be "The Relation between the Movements of the Eyes and the Movements of the Head."

CAMBRIDGE.—Mr. W. G. P. Ellis, of St. Catharine's College, has been appointed a Demonstrator in Botany.

Applications for permission to occupy the University's tables at the Naples Zoological Station, and the Marine Biological Laboratory at Plymouth, are to be sent to Prof. Newton, Magdalene College, by May 23.

The Syndicate for Advanced Study and Research have proposed new statutes for carrying out the scheme recently approved by the Senate, and have extended the scheme so as to include advanced students in law who are graduates of other Universities.

The honorary degree of Doctor of Science is to be conferred on Mr. Francis Galton, F.R.S.

MR. A. E. TUTTON has been appointed Inspector of Schools and Classes under the Science and Art Department.

THE Report of the Council of the City and Guilds of London Institute, upon the work of the Institute during the year 1894, has just been issued. The Council expressed their satisfaction at the renewal of the contribution of the Corporation of London to the funds of the Institute. Special subscriptions have been received, or promised, from the Salters' Company, in addition to their annual subscription, for the encouragement of chemical research; from the Cordwainers' Company, in addition to their annual subscription to the Institute, and the Leather Trades' School, for the inspection of classes in boot and shoe manufacture in connection with the Technological Examinations Department, and, for the first time, from the Tylers' and Bricklayers' and the Coachmakers' Companies. The proposal of the Salters' Company to place at the disposal of the Institute a sum of £150 a year to be applied to founding one or more Fellowships, to be entitled the Salters' Company Research Fellowships for the encouragement of higher research in Chemistry in its relation to manufactures, has already been referred to in these columns. The scheme for the

administration of this grant, prepared by a Special Committee of the Institute and adopted by the Executive Committee, has since received the sanction of the Court of the Salters' Company. The first award was made in January of the present year to Dr. Martin O. Forster. A sum of £333 4s. 3d. has also been received from the Committee of the Siemens Memorial Window Fund, "as an endowment to furnish a small sum to the recipient of the Siemens Memorial Medal, which is awarded annually to the student of the greatest merit in the Department of Electrical Engineering at the Central Technical College of the City and Guilds of London Institute." The Report deals in detail with the operations of the several colleges, schools, and departments of the Institute's work.

MISS GRACE CHISHOLM has just taken the degree of Doctor of Philosophy at Göttingen, this being the first degree obtained by a lady since Göttingen became a Prussian University. Miss Chisholm was a scholar of Girton College, Cambridge, and was placed between the 22nd and 23rd Wranglers in Part I. of the Mathematical Tripos in 1892, and in Class 3 of the Mathematical Tripos, Part II., in 1893. In 1892 she also took a first class in the Final Mathematical School at Oxford. After leaving Girton, she proceeded to Göttingen, and, receiving permission to attend the mathematical lectures, was in residence there about a year and a half. It was with the express sanction of the Prussian Minister of Education that the doctor's degree was conferred on her, and it is thought that the precedent thus established will probably lead to a substantial development in the opportunities offered for the higher education of women in Germany.

SILVER MEDALS have been awarded to Mr. R. H. Turnbull, Mr. G. F. Mair, and Mr. And. Robertson, of the Glasgow and West of Scotland Technical College. The medals were purchased with funds placed at the disposal of Prof. A. H. Sexton, by the West of Scotland Iron and Steel Institute, for the award of prizes for knowledge of the metallurgy of iron and steel.

SCIENTIFIC SERIALS.

American Meteorological Journal, April.—Recent foreign studies of thunderstorms: Switzerland, by R. De C. Ward. The systematic study of thunderstorms has been regularly carried on in Switzerland since 1883, and the results have been published yearly in the *Annalen* of the Central Meteorological Office, but there has been no general summary of the whole data. The general conditions of thunderstorm development in Switzerland are the presence of cyclonic depressions over Northern Europe, high temperatures, southerly winds and secondary depressions over Switzerland. Note on Croll's glacial theory, by Prof. W. M. Davis. This is a reprint from the *Transactions* of the Edinburgh Geological Society (vol. vii.). The author thinks that the recent studies of Dr. J. Hann, on the origin of cyclones and anti-cyclones, suggest an amendment to Croll's physical explanation of the climate of the glacial period.

Symons's Monthly Meteorological Magazine, April. Earth temperatures and water-pipes, by the Editor. A table shows the earth temperatures at nineteen stations in various parts of the country, from which it is seen that frost penetrated to 1 foot at eleven stations, to 1 foot 6 inches at three stations, to 2 feet at one station, and nowhere reached 2 feet 6 inches. The fact that ice formed in many pipes buried 2 feet 6 inches, and probably lower, is indisputable, but the explanation is not given of the apparent discordance between the temperature of the water and that shown by the earth thermometers.—The great gale in the Midlands on March 24, by H. A. Boys and A. W. Preston. This appears to have been, locally, one of the heaviest gales for many years. In a park near East Dereham, it is said that 1100 trees were uprooted. The worst part of the hurricane was from 1h. 30m. to 2h. 15m. p.m., and both observers state that the gusts were little short of force 12 of the Beaufort scale, which is equivalent to a velocity of ninety miles in the hour.—Snow from a cloudless sky, by C. L. Prince. The author states that at Crowborough, Sussex, on February 6, some snow crystals and minute spiculæ of ice fell at intervals, without any visible cloud.

L'Anthropologie, 1895, tome vi. No. 1.—Note sur l'âge de la pierre en Ukraine, par M. le Baron de Baye. The author collected the materials for this article while residing in the province of Kiev, during the years 1893 and 1894. Little Russia contains three kinds of tumuli of the Stone age: (1) Small tumuli each containing a single skeleton resting on clay or white sand, and wrapped in birch bark; and in which small stone arrow-heads are found, but no stone implements of large size. (2) Cists, constructed of stone slabs, containing vases filled with ashes and burnt bones, with which are associated polished stone weapons. (3) Tumuli containing skeletons, certain parts of which, particularly the bones of the head, are coloured red. Opinions differ as to whether this colouration has been produced naturally or artificially; but the interments may probably be referred to the end of the Stone age, as only three bronze relics have been found in sixty of these tombs opened by Prof. Antonowitch.—La sculpture en Europe avant les influences gréco-romaines, par M. Salomon Reinach. In this number the author describes and figures relics of the Bronze age, chiefly swords and dagger hilts, many of them of great beauty.—De l'art du potier de terre chez les Néo-Calédoniens, par M. Glaumont. The pots of the New Caledonians are made of clay; they are spheroidal in shape, and have large mouths, the lips of which are turned over and pierced with two, or sometimes four, holes, through which a cord is passed to facilitate transportation from one place to another. They never have feet, but, when used for cooking, are either supported on two or three stones fixed in the ground, or they are suspended from a branch driven obliquely into the earth so as to project over the hearth. The ornamentation is usually very simple, consisting merely of lines, but on one vase from the north of the island, figured by M. Glaumont, there appears a human face in relief.—Les races de l'Ogooué. Notes anthropologiques, par M. Liotard. It is now fully recognised that the population of the Gaboon consists of several peoples of different types, each having special characteristics. M. Liotard has had exceptional opportunities of studying these people, and here records some of the results of his observations.

IN Nos. 1–4 of the *Bullettino* of the *Società Botanica Italiana* for 1895 is an article by Sig. P. Voglino, on the part played by snails and toads in the propagation of certain fungi. In the digestive canal of these animals he found abundance of the spores of species of *Russula*, *Tricholoma*, *Lactarius*, and other species of Agaricini. The faculty of germination of these spores had not been destroyed by passing through the body of the animal. Sig. A. De Bonis contributes a paper on the cleistogamous flowers of *Portulaca grandiflora*, *Salpiglossis sinuata*, and *Lamium amplexicaule*. The production of these flowers he attributes to unfavourable vital conditions, especially sterility of the soil. The remaining articles are chiefly of interest to Italian botanists.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, April 26.—Mr. Walter Baily, Vice-President, in the chair.—Prof. S. P. Thompson read a note on a neglected experiment of Ampère. Ampère, in 1822, made an experiment which, if it had been properly followed up, must have led to the discovery of the induction of electric currents nearly ten years before the publication of Faraday's results. While attempting to discover the presence of an electric current in a conductor placed in the neighbourhood of another conductor, in which an electric current was flowing, Ampère made the following experiment. A coil of insulated copper strip was fixed with its plane vertical, and a copper ring was suspended by a fine metal wire, so as to be concentric with the coil, and to lie in the same plane. A bar magnet was so placed that if an electric current was induced in the suspended ring, a deflection would be produced. No such deflection, however, was observed. In 1822, in conjunction with de la Rive, Ampère repeated this experiment, using in place of the bar magnet a powerful horse-shoe magnet. He describes the result in the following words: "The closed circuit under the influence of the current in the coil, but without any connection with this latter, was attracted and repelled alternately by the magnet, and this experiment would, consequently, leave no doubt as to the production of currents of electricity by induction if one had not suspected the presence of a small quantity of iron in the copper of which the ring was formed." This closing remark shows that they were looking for a permanent deflection. When, however, Faraday's results were published in 1831, Ampère, after again describing the experiment made in 1822 by himself and de la Rive, says:—"As soon as we connected a battery to the terminals of the conductor the ring was attracted

or expelled by the magnet, according to the pole that was within the ring, which showed the existence of an electric current produced by the influence of the current in the conducting wire. Verdet, when describing the above experiment, falls into a curious error. He says the apparatus consisted of a ring of fine copper wire, suspended by a silk thread in front of the pole of an electromagnet in such a way that the plane of the ring was parallel to the plane of the turns of wire on the electromagnet. On "making" the current the ring is said to have been repelled, but this deviation did not persist, and on "breaking" the current the ring was attracted, also only momentarily. Mr. Blakesley did not feel quite confident that in Verdet's form of the experiment there could ever be attraction. He also pointed out that with an alternating current the disc would tend to set itself parallel to the lines of force of the electromagnet. With reference to repulsion by alternating currents in one of Elihu Thompson's experiments where a sphere is supported over an alternating pole, a screen being placed so as to partly shield this sphere, there is generally a misstatement as to the direction in which the sphere rotates. It rotates in such a direction that the part of its surface next the magnet moves towards the edge of the screen. Dr. Burton said that from the fact that when the current in the electromagnet in Verdet's experiment is broken, the induced current in the ring is in the same direction as the current in the magnet, the ring will be attracted. Mr. Boys confirmed Dr. Burton's statement. He recommended setting the ring at an angle of 45° to the lines of force, under which circumstances a rotation would be obtained. A distinction must, he pointed out, be drawn between such an experiment as that of Verdet and those of Elihu Thompson. The repulsions observed in these latter were only due to the "lag" in the induced currents caused by self-induction. The best materials to use for all such experiments were magnesium and aluminium, since for a given mass these had the highest conductivity. – Mr. W. G. Rhodes read a paper entitled "A theory of the Synchronous Motor." The object of this paper is to give as simple a treatment as possible of the mathematical part of the subject, and to give theoretical proofs of some experimental facts. Starting from the energy equation

$$p + c^2R = cE\cos\psi$$

where p is the output of the motor, R the resistance of the armature, c the current through the armature, E the E.M.F. applied to the motor terminals, and ψ the phase difference between c and E the cases of maximum output, zero output, minimum current at zero power, and maximum phase difference between c and E are considered. These results are, for the most part, obtained directly from the energy equation. The latter part of the paper is devoted to a discussion of the phase relationships between the current and the E.M.F.s in a plant consisting of a generator and motor, and to the variations in the armature reactions in both generator and motor. A theoretical proof is given of the fact, observed by Prof. Silvanus Thompson and others, that an over-excited synchronous motor acts as a condenser, and tends to make the current lead before the generator's E.M.F. Prof. S. P. Thompson said that the mathematical part of the paper was much simpler than that in previous investigations on this subject, and the method of arriving at the results by rejecting imaginary roots of the equations was particularly neat and instructive. The part of the paper relating to armature reactions and phase relationships was quite new. Two results deserved special attention: first, that the maximum current at zero power was the same as if the circuit was non-inductive; second, that the maximum current zero power was double the current corresponding to maximum output. Mr. Blakesley said that the paper did not consider the stability of the system, and he thought some of the results corresponded to regions of unstability. A paper by Mr. Bryan, "On a simple graphical interpretation of the determinantal relation of dynamics," was, in the absence of the author, read by Dr. Burton. The relation is worked out for two specially simple systems possessing one degree of freedom: (1) a particle moving in a straight line with uniform acceleration; (2) a particle moving to and fro along a straight line with an acceleration directed towards a fixed point on the line, and proportional to the distance from that point (simple harmonic motion). On constructing a diagram in which the abscissæ represent values of the single coordinate of the particle, and the ordinates the corresponding values of the momentum, the determinantal relation becomes equivalent to the constancy of the area of a certain elementary parallelogram. In case (1) this parallelogram moves along a parabola, experiencing a shear as it goes, while in case (2) there is no distortion, the (rectangular) parallelogram revolving about the origin of the diagram as if rigidly attached to an inextensible radius vector.

Linnean Society, April 18. Mr. C. B. Clarke, F.R.S., President, in the chair.—In view of the approaching anniversary meeting, the election of auditors was made, when Mr. A. D. Michael and Prof. J. R. Green were nominated on behalf of the Council, and Messrs. E. M. Holmes and H. Groves on behalf of the Fellows.—Mr. T. B. Blow exhibited specimens of the river-weed *Mourera fluviatilis*, Aublet, from the River Essequibo, with observations on its life-history, and lantern slides illustrating the natural haunts of the plant.—Mr. J. E. Harting exhibited and made remarks upon a collection of West African Lepidoptera which had been collected and forwarded by Mr. J. T. Studley from Old Calabar, and was to be presented to the British Museum.—Mr. Howard Saunders exhibited a specimen of the European white-winged Crossbill, *Loxia bifasciata*, which had been shot in co. Fermanagh in February last, and was lent for exhibition by Mr. C. Langham.—Some photographs of English Red-deer heads, showing successive growths of antlers in the same stag by comparison of the shed horns, were exhibited on behalf of Mr. Lucas, of Warnham Court, Horsham.—A paper was then read by Mr. F. W. Keeble, entitled "Observations on the *Loranthaceæ* of Ceylon," in which country the author had made a short sojourn in 1894. After remarking that in Ceylon many species of *Loranthus* have large and conspicuous flowers, with the corolla-tube brightly coloured, more or less tubular and lobed, he pointed out that certain deviations from the typical regularity of the corolla-tube were correlated with the mode of fertilisation of the flower by Sun-birds (*Nectarineæ*), and this was made clear by diagrams and some excellent coloured drawings. Discussing the mode of distribution of the seeds, Mr. Keeble first quoted the views of Engler and Prantl, and the remarks in Kerner's "Pflanzenleben" (English edition), on the dissemination of the European Mistletoe, and then detailed his own observations in the case of tropical *Loranthaceæ*. The modes of germination of various species of *Loranthus* and *Viscum* were then described, as well as the curvature and growth of the hypocotyl, and the effect of contact on the latter, and on its suctorial disc; the paper concluding with some remarks on the forms of fruit and seed of Cinghalese species of *Loranthaceæ*.—Mr. A. Trevor-Battye exhibited and made remarks upon a collection of plants obtained during his sojourn on the Island of Kolguev.

Entomological Society, May 1. – Prof. Raphael Meldola, F.R.S., President, in the chair. Dr. C. G. Thomson, of the University, Lund, Sweden, was elected an Honorary Fellow, to fill the vacancy in the list of Honorary Fellows caused by the death of Pastor Wallengren. – Mr. Waterhouse exhibited a living larva of a Longicorn Beetle. This larva was found in a boot-tree which had been in constant use by the owner for fourteen years, the last seven of which were spent in India. The specimen was brought to the British Museum on May 6, 1890, and was put into a block of beech wood in which it had lived ever since; it did not appear to have altered in any way during these five years. It had burrowed about eight inches, and probably made its exit accidentally. Mr. Blandford referred to a similar case which had come under his notice. – Mr. C. G. Barrett exhibited a long series of the dark and strongly-marked varieties of *Agrotis cursoria* and *Agrotis tritici*, taken on the sand-hills of the north-east coast of Scotland by Mr. Arthur Horne, of Aberdeen. – Mr. Dale exhibited a specimen of a Sesia – supposed to be a new species – from the New Forest. Mr. O. E. Janson exhibited a remarkable species of *Curculionidæ* from the island of Gilolo, having exceedingly long and slender antennæ and legs; it was apparently an undescribed species of the genus *Talanthia*, Pascoe. Mr. Nelson Richardson called attention to a paper by himself, in the *Proceedings* of the Dorset Natural History and Antiquarian Field Club, on the subject of Dorset Lepidoptera in 1892 and 1893. Mr. W. L. Distant communicated a paper entitled, "On a probable explanation of an unverified observation relative to the family Fulgoridæ." In the discussion which ensued, Mr. Blandford said he thought further evidence was required on the subject of the alleged luminosity in the Fulgoridæ before the statement contained in Mr. Distant's paper could be accepted. Mr. J. J. Walker, R.N., contributed a paper entitled, "A preliminary list of the Butterflies of Hong Kong, based on observations and captures made during the winter and spring months of 1892 and 1893." Prof. Meldola

commented on the interesting character of the paper from an entomological point of view, and the value of the observations therein on the geology, botany, and climate of Hong-Kong.

Geological Society, April 24.—Dr. Henry Woodward, F.R.S., President, in the chair.—On the shingle beds of Eastern East Anglia, by Sir Henry H. Howorth, F.R.S. The author has carefully examined the country around Southwold, where the beds known as Westleton beds (which might well have been associated with the name of Southwold) are developed. He alluded briefly to the recent shingle, the pebbles of which are derived from the ancient shingles of the cliffs; the formation of this shingle, he maintained, may belong to a time not far removed from our own day. Turning to the Westleton beds, he noticed that they were essentially "drifts," the component pebbles not having been shaped on the spot, but brought as pebbles from elsewhere; and he gave reasons for supposing that they were derived from pebbly beds in the Lower London Tertiary group and in the Red Crag. He also maintained that the shells of the Westleton beds and Bure Valley beds were derived from crag deposits. Reasons were given for supposing that the pebbles of the Westleton shingle of East Anglia came from the west, and that this moved eastward from the plateau of Suffolk towards the sea. It was considered that these beds can only be explained by a tumultuous diluvial movement.—Supplementary notes on the systematic position of the Trilobites, by H. M. Bernard. Since the publication of a paper by the author in the *Quarterly Journal of the Geological Society* for 1894, two important papers by Dr. Beecher have appeared, giving details as to the structure and appendages of *Triarthrus*. The author, therefore, returned to the subject, and discussed in detail the more recent discoveries in the light of the affinity between *Apus* and the trilobites. He endeavoured to show how the results obtained by Dr. Beecher bear on the larger question as to the suggested origin of both of these animals from a chaetopod annelid modified in adaptation to a new manner of feeding. An experiment to illustrate the mode of flow of a viscous fluid, by Prof. W. J. Sollas, F.R.S. The author, recognising that it is by a knowledge of the laws of viscous flow that we must seek to extend our information concerning the movements of flowing ice, conducted an experiment, the details of which were described, with a model of a glacier composed of the modification of pitch usually known as "cobbler's wax." In the model the pitch moved under its own weight over the horizontal floor of a trough, which was crossed by a barrier to represent an opposing mountain or the rising end of a lake. The results of the experiment showed that the movement of the pitch-glacier was not confined to that portion of it which rose above the barrier, but extended throughout its mass, and that an upward as well as forward movement took place as the barrier was approached. Thus the transport of stones by glaciers from lower to higher levels was by no means an incredible phenomenon, but a necessary concomitant of such simple conditions as those assumed in the experiment.

Malacological Society, April 19.—Dr. H. Woodward, F.R.S., Vice-President, in the chair. In addition to specimens in illustration of authors' papers, the following were shown: Mr. A. S. Kennard exhibited a series of Mollusca from a Pleistocene deposit at Crayford; Mr. S. Pace exhibited two species of *Estheria* from Persia and S. Algeria; Mr. W. M. Webb exhibited mollusca from a Pleistocene deposit at Chelmsford; Mr. E. R. Sykes exhibited a distribution chart of *Clausilia*.—The following communications were read: On some new species of British Mollusca from the *Triton* Expedition, by H. K. Jordan.—The Anatomy of *Natalina caffra*, Fer, by M. F. Woodward.—Descriptions of new species of Mollusca of the genera *Bullia*, *Mangelia*, *Trochus*, &c., from the Mekran Coast, by G. B. Sowerby.—List of Land and Freshwater Mollusca from New Providence Isle, Bahamas, by W. Bendall.—Notes on two cases of the transport and survival of Terrestrial Mollusca in the New Forest, by T. Leighton.

Royal Microscopical Society, April 17.—Mr. A. D. Michael, President, in the chair.—The Secretary said they had received a valuable donation from the South London Microscopical and Natural History Club, in the shape of a lantern with microscope attachment.—Mr. A. Letherby read a short paper upon the structure of the Podura scale.—The President read a paper on the structure of the brain in the Oribatidæ and in some other Acarina.

CAMBRIDGE.

Philosophical Society, April 29.—Exhibition of *Palophus tiaratus* (a stick-insect from Mashonaland), by Dr. D. Sharp.—A modified method of finding the specific gravities of tissues, by Dr. Lazarus-Barlow. The author showed an improved method of finding the specific gravity of tissues. In a research on the pathology of the œdema which accompanies passive congestion, published in the *Philosophical Transactions* of the Royal Society, he used the solutions made up with glycerine introduced by Roy for the estimation of the specific gravity of blood, but found that difficulty arose from the large quantity of muscle used in obtaining the correct specific gravity, and from the fact that the glycerine abstracts water from the muscle with such rapidity that after a very few seconds the piece of muscle invariably sank. He therefore has used for the past year solutions of various specific gravities made with gum arabic, which he arranges in a wide test-tube in their order of density. Alternate layers are coloured blue. Diffusion occurs with extreme slowness, so that 48 hours after arranging the test-tube the various layers are quite evident. The special advantages of the method are that one piece of muscle is sufficient for an estimation, as it sinks through the layers of lower specific gravity until it reaches that layer with which it is identical; that water is abstracted from the muscle by gum much more slowly than by glycerine, and that, as has been shown by Heffter, the vitality of cardiac muscle is better maintained by gum arabic solutions than by any other solution.—Crania of native tribes of the Panjab, by Prof. Macalister.

PARIS.

Academy of Sciences, April 29.—M. Marey in the chair.—A projected balloon expedition to the Arctic regions, by M. S. A. Andrée. The author defines the conditions necessary to be fulfilled by a balloon destined for Arctic exploration, and shows that such conditions can be fulfilled. He has succeeded in obtaining a certain amount of directive power by using a rope drag to retard the progress of the balloon relatively to the wind, and then using a sail in the ordinary way. By this device a mean deviation of 27° has been secured. Sometimes a deviation of nearly 40° has been obtained. M. Émile Blanchard in connection with this paper calls attention to the probability of existence of an open polar sea, and points out the support this view receives from the many flocks of web-footed birds observed making their way northwards by explorers when nearest to the pole.—On the double points of a group of algebraical surfaces, by M. G. B. Guccia.—On the types of groups Ω of substitutions, of which the order equals the degree, by M. R. Levavasseur.—On an application of M. Darboux's method (mathematical analysis), by M. Beudon.—On the rotation of solids, by M. R. Liouville.—On a class of periodic solutions in a particular case of the problem of three bodies, by MM. J. Perchot and J. Mascart.—Measurements of the intensity of gravity in Russia, by M. G. Defforges. Data are given for Pulkowa, Tiflis, Ouzoun Ada, Bokhara, and Tashkend, from which it is shown that the negative continental anomaly is very pronounced at Ouzoun Ada and Tashkend, and at Bokhara is of the same order as at Paris; the positive anomaly is greater than previously observed at Pulkowa.—On the specific heat of superfused liquids, by M. Louis Bruner. Thymol and paracresol give specific heats increasing with the temperature range when cooled without solidification to approximately the same extent below their melting-points for each experiment. Menthol and bromal and chloral hydrates cannot be obtained superfused by cooling.—On the solidification of some organic substances, by M. Louis Bruner.—On the regularity of luminous movement, by M. Gouy.—On the electric resistance of saccharine liquids, by MM. Gin and Leleux. Expressions are given showing the relationships between resistance and the concentration and temperature of saccharine solutions. The resistance is shown to be a function of the current density. This result is explained on the Arrhenius hypothesis as due to the state of ionisation of the badly conducting electrolyte.—New researches on the heats of combination of mercury with the elements, by M. Raoul Varet.—On the action of the halogen compounds of phosphorus on metallic copper, by M. A. Granger. Copper phosphide, CuP_2, is produced by passing phosphorus trichloride vapour in carbon dioxide over slightly heated copper; cuprous chloride is formed at the same time and deposited at the end of the tube. PBr_3 and PI_2 give the same compound. PF_3 needs a red-heat, and produces Cu_5P_2.—Researches on manganese, by M. Charles Lepierre. The manganic-ammonium

sulphate is described in addition to hydrated and anhydrous ammonium-manganous sulphate.—Campholenic acids and amides, by M. A. Behal. Isomeric acids and amides have been obtained. The solid acid was thought to be the racemic form of the liquid acid, but all attempts to separate optical isomers have failed.—Double combinations of anhydrous aluminium chloride with nitro-compounds of the aromatic series, by M. G. Perrier. A series of compounds of the type $Al_2Cl_6 . 2C_6H_4 . CH_3 . NO_2$ (1 : 4) are described, and it is shown that with nitro-derivatives of the type of paranitrotoluene, Friedel and Crafts' reaction fails.—On a possible error by the use of Fehling's solution for the estimation of sugar in urine from persons submitted to treatment with sulphonal, by M. Ph. Lafon. On the panification of brown bread, by M. James Chappuis.—On the causes which produce the colour of brown bread, by M. Léon Boutroux. Gluten may give the colour in bread by desiccation, but not by fermentation. By oxidation with air in presence of water, bran may produce the colouration of bread; but, again, fermentation has no such effect. The acidity of the yeast is a protection against browning.—On the ethology of the genus *Thaumaleus Kroyer*, by M. Alfred Giard.—Observations on the hornets, by M. Charles Janet.—New researches on "la brunissure," by M. F. Debray.—Action of static sparks on the local temperature of regions submitted to this method of franklinisation, by M. H. Bordier.—Treatment of a case of sarcoma by serotherapy, by MM. J. Hericourt and Ch. Richet. The catastrophe of Laibach, April 14, 1895, by M. Ch. V. Zenger.

Washington.

National Academy of Sciences, April 16–20. On some variations in the genus Eucope, by A. Agassiz and W. McM. Woodworth; notes on the Florida reef, by A. Agassiz; the progress of the publications on the expedition of 1891 of the U.S. Fish Commission Steamer *Albatross*, Lieut.-Commander Z. L. Tanner commanding, by A. Agassiz; on soil bacteria, by M. P. Ravenel; a linkage showing the laws of the refraction of light, by A. M. Mayer; on the colour relations of atoms, ions and molecules, by M. Carey Lea; mechanical interpretation of the variations of latitude, by R. S. Woodward; on a new determination of the nutation-constant, and some allied topics, by S. C. Chandler; on the secular motion of a free magnetic needle, by L. A. Bauer; on the composition of expired air, and its effect upon animal life, by J. S. Billings; systematic catalogue of European fishes, by Th. Gill; the extinct cetacea of North America, by E. D. Cope; on the application of a percentage method in the study of the distribution of oceanic fishes (1) definition of eleven faunas and two sub-faunas of deep sea fishes, (2) the relationships and origin of the Carribeo-Mexican and Mediterranean sub-faunas, by G. Brown Goode; on the two isomeric chlorides of ortho-sulpho-benzoic acid, by Ira Remsen; on some compounds containing two halogen atoms in combination with nitrogen, by Ira Remsen; presentation of the Watson Medal to Mr. Seth C. Chandler, for his researches on the variation of latitudes, on variable stars, and for his other works in astronomy; biographical memoir of Dr. Lewis M. Rutherfurd, by B. A. Gould; relation of Jupiter's orbit to the mean plane of four hundred and one minor planet orbits, by H. A. Newton; orbit of Miss Mitchell's Comet, 1847 VI, by H. A. Newton.

New South Wales.

Linnean Society, March 27.—Prof. David in the chair. The President delivered the annual address, in the course of which reference was made to the recent suit in the Equity Court, in which the Society was defendant, brought by the University of Sydney to obtain the declaration of the Court as to the construction of so much of the will of the late Sir William Macleay as relates to his bequest of £12,000 for the endowment of Bacteriology; and the full text of the judgment of his Honour the Chief Judge in Equity was read. After summarising the contributions to science made during the year by the various local scientific institutions and departments, the President passed on to consider at some length the subject of recent research in the Arctic and Antarctic regions, and especially the important position outlined by Dr. John Murray, namely, that of the desirability of a thorough and systematic exploration of the whole Antarctic region with all the appliances of the modern investigator. The following gentlemen were elected office-bearers and Council for 1895. President: Henry Deane. Vice-Presidents: Dr. James C. Cox, Prof. W. A. Haswell, Prof. T. W. E. David. Treasurer: The Hon. James Norton. Council: John Brazier, Cecil W. Darley, Thomas Dixson, J. R. Garland, Arnold U. Henn, A. H. S. Lucas, J. H. Maiden, C. J. Martin, Perceval R. Pedley, P. N. Trebeck, Thomas Whitelegge, Prof. J. T. Wilson.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Elements of Health: Dr. L. C. Parkes (Churchill).—A Treatise on Practical Chemistry: Dr. F. Clowes, 6th edition (Churchill).—Chemical Technology, edited by Groves and Thorp. Vol. 2. Lighting (Churchill).—Fern-Growing: E. J. Lowe (Nimmo).—Le Centenaire de l'École Normale (Paris, Hachette).—Le Cause dell' Era Glaciale: L. de Marchi (Pavia, Fratelli Fusi).—Die Lehre von der Elektrizität und deren Praktische Verwendung: Th. Schwartze (Leipzig, Weber). Physikalische Krystallographie: P. Groth, Dritte Auflage, 3 Abthg. (Leipzig, Engelmann).—Low's Chemical Lecture Charts (Low).—Die Photographie ein Handbuch für Fach-und Amateur-Photographen: A. Hertzka (Berlin, Oppenheim).—Object-Lessons in Botany: E. Snelgrove, Book 2 (Jarrold).—Dakota Grammar, Texts and Ethnography: S. R. Riggs (Washington).—Eleventh and Twelfth Annual Reports of the Bureau of Ethnology: J. W. Powell (Washington).

Pamphlets.—Royal Gardens, Kew: Official Guide to the Museums of Economic Botany, No. 2 (London). The Franklin Institute: W. H. Wahl (Philadelphia). Royal Gardens, Kew: Hand-List of Ferns and Fern-Allies cultivated in the Royal Gardens (Eyre and Spottiswoode). Myodes lemmus, its Habits and Migrations in Norway (Christiania).—List of the Publications of the Bureau of Ethnology, &c. (Washington).—An Ancient Quarry in Indian Territory: W. H. Holmes (Washington).

Serials.—Humanitarian, May (Hutchinson).—Record of Technical and Secondary Education, April (Macmillan).—British Moss-Flora: Dr. R. Braithwaite, April (the Author, Clapham Road).—Botanische Jahrbücher für Systematik, Pflanzengeschichte und Pflanzengeographie, Zwanzigster Band, 3 Heft (Leipzig, Engelmann). Fortnightly Review, May (Chapman).—Internationales Archiv für Ethnographie, Band viii. Heft 2 (Leiden, Brill).—Philosophical Society of Washington, Bulletin Vol. xiii. pp. 31–76 (Washington). Zeitschrift für Physikalische Chemie, xvi. Band, 4 Heft (Leipzig, Engelmann). L'Anthropologie, tome vi. No. 2 (Paris, Masson).—Scribner's Magazine, May (Low).—Geological Magazine, May (Dulau). Quarterly Journal of the Geological Society, Vol. li. Part 2, No. 202 (Longmans).—Geographical Journal, May (Stanford).

CONTENTS.

THURSDAY, MAY 16, 1895.

HYGIENE AND METEOROLOGY.

Hygienische Meteorologie. Für Ärtze und Naturforscher Von Prof. Dr. W. J. van Bebber, Abtheilungs Vorstand der deutschen Seewarte in Hamburg. (Stuttgart: Ferd. Enke, 1895.)

NO long preface is needed to prove that meteorology and hygiene have a close and intimate connection, or that the study of both sciences may be mutually helpful. The exhibition of a small death-rate does not exhaust the whole of the problems with which hygiene busies itself. All that tends to ameliorate the condition of the human race, all that ministers to the comfort or promotes the well-being of the individual, is cared for by the student of hygiene. That climate and the phenomena, which we recognise under the comprehensive term "weather," have an intimate connection with the health and comfort of the race, will not be seriously denied, whatever different views may be held as to the precise manner, and to what degree, the condition of the atmosphere can operate on individual cases. Some knowledge of meteorology has hitherto been demanded from candidates for diplomas in sanitary science, public health, or State medicine; and, judging from the rules adopted by the Council, December 1, 1893, the conditions of the examination will in future demand a still closer acquaintance, since the applicant is required to show the possession of a "distinctively high proficiency, scientific and practical, in all the branches of study which concern the public health." To those who seek something more than a bare superficial knowledge of meteorology, this book will be very welcome, and not only to those who desire diplomas, but to the larger, though less specially instructed, class who desire the welfare of the human family.

Coming from one the direction of whose scientific studies is distinctly meteorological, it might be anticipated that the book would deal more with this subject than with hygiene; and to some extent this is the case, and possibly the interest in the book will on this account be diminished. We have a collection of facts, admirably arranged, though drawn, of course, mostly from German sources; and such a collection will be of the greatest value to some student of sanitary and social science, who, trained in physiological schools, will produce a work of greater interest, more closely connected with the spread and mitigation of disease as affected by climate or meteorological conditions of a more or less temporary character. In one important respect, however, the book deviates from the generality of meteorological treatises, and at the same time removes an objection which has frequently been urged by physicians, who assert that weather statistics are not given in the form which is most convenient or most instructive. To take a mean of his observations is too frequently the sole aim of the meteorological observer, and consequently mean results for temperature, for example, are given, where the range of variation is the more important element from the medical point of view. This fact is fully recognised by the author, and he deals not only with the mean values, but also with the amount of variation from the arithmetic mean and the frequency with which such variations occur.

The book is divided into eight sections. The two first treat of the physical properties and of the various ingredients of the air. Elementary physics characterises the first, chemistry the second. In this latter section are described somewhat fully the gases which enter into the atmosphere, not excepting those which are present in minute quantities. Accidental ingredients, such as dust and micro-organisms, are also considered. One does not meet with anything very new, but the facts are well and pleasantly arranged, and would give any student all the information necessary for fully comprehending the successive chapters. It might have been expected that the constituents of water would have been treated with the same degree of fulness. Free oxygen in water may not be of the same importance as in the air, but the aëration of water is not insignificant, whether regarded as an important withdrawal from the atmosphere itself, or the part it plays in the oxidation of organic material, be it in the form of ozone or hydrogen dioxide, or other efficient oxidiser.

The chapter on Temperature is admirable. From a vast collection of material with which intimate study has made the author closely familiar, he is able to systematise and arrange those facts which have the greatest and most obvious bearing on the subject. It is a graphic digest of all that affects the temperature of the world, and is amply illustrated by tables compiled from many sources. We wish we could pay him a compliment on his maps. In the map on page 110 it is only with great difficulty that Europe is recognised, and the one on page 174 is very little better. The tables are, however, so very well arranged, that this slight defect is of little consequence.

As an illustration of the minuteness into which the author enters, we may quote the measures of the temperature of different parts of clothing when worn. The figures have been reduced to Fahrenheit scale, in which form, if less scientific, they may be of use to some of the commercial firms who are interested in such matters.

	Temp. 50°	Temp. 79°
Temp. on the coat	71°·2	82°·4
,, between coat and vest ...	73·6	83·8
,, ,, vest and linen shirt	75·9	84·7
,, ,, linen shirt and woollen shirt ...	77·4	85·3
,, ,, woollen shirt and skin	90·9	89·8

The loss of temperature which the body experiences at a temperature of 59° is diminished by clothing in the following proportions:—

Radiation from the bare skin	100
,, when covered with wool	73
,, when covered with wool and linen ...	60
,, when covered with wool, linen, and vest	46
,, when fully dressed	33

It does not appear whether the velocity of the wind has been taken into account in deriving these figures. The importance of clothing comes, however, again to the fore

as affected by moisture, where the author computes and illustrates the amount of heat abstracted from the body in order to convert into vapour the water which a saturated suit of clothes is capable of containing.

This latter remark has reference naturally to the chapter on Precipitation, which, with the following one on Thunder-storms, does not call for any special remark. Emphasis is laid on the purifying influences that rain and snow have on the atmosphere; but little is said, perhaps, because little is known with certainty, of cleansing influences on water. The question how far water once contaminated can be restored to its original organic impurity, without the processes of evaporation and reprecipitation, has exercised the minds of chemists and sanitarians in this country with some severity. Information is still necessary both as to the processes at work and the agents by which impurities are removed, as they admittedly are, by some self-cleansing method. The author is understood to recommend filtration as especially necessary to eliminate *auszuscheiden* bacteria, presumably bacteria of a pathogenic character. He does not seem to recognise the fact, if it be a fact, that a filter-bed covered with bacteria has still the power of arresting in a very considerable degree the bacteria in the water that filters through it. How this is accomplished is another matter, which may not concern meteorology, but the large questions of sedimentation and percolation of water in its passage through the ground comes naturally into the treatment by Dr. Bebber, more especially as he enters with some degree of detail into ground water, and the conditions which make it potable or otherwise.

Wind and the motion of cyclones are subjects that the author has made peculiarly his own, and are dealt with here at considerable length. Considering the important results that follow the transport of masses of air from place to place, and the mingling and purification of the atmosphere that is thus effected, it is not suggested that the subject receives an undue amount of attention. The connection between cyclonic paths (*Zugstrasse*) and hygiene, however, is not so immediately evident; but the subject is one that has long interested Dr. Bebber, and he naturally has much to say. It is meteorology pure and simple, and has this defect, that it is scarcely full enough for the student of that science, and in too great detail for the sanitarian.

Perhaps the most interesting chapter in the book is the last, on Climate, and in which is treated diseases under various climatic conditions. On page 275 is given a table showing the annual mortality per thousand in various parts of the world. This table is apparently thrown together haphazard, and does not exhibit that careful arrangement by which Dr. Bebber in other parts of his book has illuminated his work and instructed the student. But the bald facts, as written down, gain by that very absence of symmetry, and are both interesting and gratifying. It is true, as the author is careful to point out, that the facts have been gathered under very various circumstances, under various authorities and systems, and are not strictly comparable; but making every allowance for inexact compilation, they do exhibit a manifest improvement in the health of nations, and bear a gratifying testimony to the successful study and practical enforcement of sanitary laws. The few samples we can extract illustrate best the increased adaptibility of individuals to meet those conditions that are generally regarded as adverse to health and longevity. Take the case of British troops in India:

From 1800–1830.	Annual death rate per thousand		...	84·6
,, 1830–1856.	,,	,,		57·7
,, 1869–1878.	,,	,,		19·3
,, 1879–1887.	,,	,,		16·3

From the West Indies the evidence is of the same character:

From 1820–1836.	European Troops,	Jamaica,	Mortality		121
,, 1817–1846.	,,	,,	West Indies	..	75
,, 1879–1887.	,,	,,	Jamaica	..	11·0
,, 1820–1830.	Negro Troops,		Jamaica	..	30·0
,, 1879–1887.	,,	,,	,,	..	11·6

On the Gold Coast, the figures are so remarkable that that they can only be explained by supposing some different method of computation to have been employed in the two circumstances:

From 1829–1836.	European Troops,	Gold Coast		...	483!!
,, 1879–1885.	,,	,,	,,	...	68

Possibly a similar source of error will explain the only retrograde case to be met with, for which the insalubrious climate of Cayenne is responsible:

From 1819–1849.	Troops,	Mortality	...	27·2
In 1855	,,	,,	...	90·8

Of course some of these beneficent results may be attributed to greater care in the selection of men to be sent to these regions; but it would be distinctly wrong to deny also that much is due to insistence on improved conditions of residence, of clothing, of food and drink, especially in the maintenance of uncontaminated sources of drinking water, in fact an insistence on those conditions which sanitary science has shown to be of the utmost importance to individuals and nations.

Possibly, enough has been said here to show that we have to do with a very interesting book, and one far reaching in its aims. If we have to make any complaint, it is only to express the regret that it is not more so. It is the omissions that are sometimes disappointing, the contents never are. We give, in conclusion, one last illustration. Remembering that the book is issued from Hamburg, and that this town suffered severely from the scourge of cholera in 1892, one cannot but feel that the Observatory is in possession of facts which could not but be of interest in discussing the vexed question of the spread of this disease. Beyond the slightest possible mention on p. 287, the author does not refer to it. Yet it is suggested that he could have told us authoritatively what meteorological conditions coincided with the greatest spread of the disease, that he could have given us details of the temperature of the ground and of the Elbe water (see p. 147) that presumably favoured the increase of the bacillus, if it did not come within his province to discuss any differences of morphology, of virulence, or reproductive faculty in the vibrio.

MECHANICAL ENGINEERING.

A Text-book of Mechanical Engineering. By Wilfrid J. Lineham, Head of the Engineering Department at the Goldsmiths' Company's Institute, New Cross. (London: Chapman and Hall, Limited, 1894.)

MR. LINEHAM says that the desirability of writing his book was suggested to him by the initiative of the City and Guilds of London Institute in providing an examination in mechanical engineering. In preparing students for this examination he was led, he says, "to consider seriously (1) whether the whole theory and practice of mechanical engineering, or even a *précis* of it, could be compressed into one volume; and (2) whether it was desirable so to compress it." After examining Mr. Lineham's book, we must confess to feeling grave doubt whether the second question, at least, should not have been answered in the negative before he set about the execution of so very large a task. The ambition of the attempt is, perhaps, more conspicuous than its success; at the same time the book has good features, and students of engineering may learn from it much that will be valuable to them. It is a novel contribution to engineering literature; by no means wholly satisfactory, but still one that should take a useful place.

Mr. Lineham deprecates in advance the criticism which he expects will be made on the compression of a vast subject into a single volume, by citing "the examples of great and successful writers—to wit, Rankine, Ganot, Deschanel, and others." We do not know whether both adjectives are intended to apply to Ganot and Deschanel, who, in any case, did not write on a subject which has a practice as well as a theory. As to Rankine, who certainly did write great and successful treatises on engineering, the citation seems particularly unfortunate. To compress everything into one volume was exactly what Rankine did not do. He wrote four or five large books dealing with various branches of the subject, and did not hesitate to repeat certain portions in more than one book whenever that was necessary to make each intelligible apart from the rest. Rankine's method and the author's are as wide apart as the poles; and of the two we prefer Rankine's. Moreover, Rankine, in his great series of text-books, dealt almost wholly with the *rationale* of engineering; but here, in a single volume, more than half the space is occupied by a description of the processes of the workshop.

It is in the descriptive portions that Mr. Lineham is at his best. Probably no better general account of hand and machine tools, and of the way to use them, has been published. The pattern shop and foundry, the smithy, the machine shop, fitting and erecting shops, all come in for their due share of attention. The construction of a horizontal engine is selected as a typical case, and is described from start to finish with minuteness of detail and with the aid of many admirable drawings. The illustrations of the book are indeed excellent throughout, both in style and matter. They are illustrations that really illustrate. There are 732 of them, and all are engineers' drawings. They have been prepared with obvious care, and it would seem with unsparing labour on the author's own part. They are treated in a way which allows of their liberal introduction without much expenditure of space. In a word, they are everything that the illustrations in such a text-book ought to be. The descriptive section of the book concludes with a useful chapter on boiler-making and plate work, with a somewhat extended account of hydraulic rivetting processes, and with a short notice of electric welding. In setting forth so much descriptive matter as this first part includes, it is of course difficult to preserve in all parts a proportion to which exception may not be taken. We could wish to have seen more space given to the milling processes, which take so prominent a place in modern workshops. Nine or ten pages for hydraulic rivetting, and a mere page and a half for the universal milling machine, seems less happy a proportion than the author has generally maintained. This, however, is a small matter; and it may safely be said that any engineering pupil or apprentice will have his outlook widened, and his knowledge considerably increased, by reading the first part of Mr. Lineham's book.

To the study of the second part, however, he will do well to bring some independent criticism. The first chapter is on the strength of materials, and we had not penetrated far without finding the ground shaky. Dealing with the nature of shear stress, the author uses the symbols f_t, f_c, and f_s to indicate intensities of tensile, compressive, and shearing stress respectively, and resolves shearing stress into normal stresses inclined at 45° to it by the equation

$$f_c^2 + f_t^2 = f_s^2$$

$$\therefore \quad f_c \text{ or } f_t = \frac{f_s}{\sqrt{2}} = \frac{f}{1{\cdot}414}.$$

This is a bad start in a chapter which is to include references to such subjects as the strength of thick cylinders, the torsion of square shafts, and the effects of combined bending and twisting in crank-shafts.

Immediately after this error is the following paragraph:

"On account of the cup or wedge fracture exhibited when a specimen is broken by tearing or crushing, and for other reasons, Prof. Carus-Wilson argues that rupture takes place by shear stresses at 45°, either wholly or partially. Certain it is that the three stresses are intimately connected, and assist each other in destroying the cohesion of the particles."

We have not an intimate acquaintance with the contributions which Prof. Carus-Wilson has made to this subject; but there is no evident reason why his authority should be invoked in support of an idea which is surely as old as the testing of materials.

Turning to the paragraph headed "Strength of square shaft," we find a geometrical construction described at some length, which is apparently based on Coulomb's erroneous theory. The student who has taken the trouble to follow this will feel excusably confused or irritated when he goes on to read the subsequent lines:

"St. Venant showed, however, in 1856 that Coulomb's ring theory was not strictly applicable to any but circular sections, and gave the following:

$$\text{Moment of square section} = f_s \; {\cdot}208 s^3 \;\cdot$$

because the greatest stress does not occur at the corners. To illustrate St. Venant, Thomson and Tait have

magined the shaft to be a box full of liquid, which, if rotated, would leave the latter behind somewhat, and the apices would cause two stresses—tangential and centripetal—to act on the particles, the former only being of momental value."

Now what is the student, whether at the New Cross Institute or elsewhere, to make of this without further explanation? To introduce St. Venant and say no more than this, is surely giving either too much or not enough. The same criticism might be repeated at many other places. Under the heading of "Pillars and Struts," we are told that Euler is pronounced Oiler (this, at least, is nothing if not practical), and his formula for the stability of long columns is quoted without explanation. Gordon's formula and constants are also quoted, and the subject is dismissed with the dictum:

"Claxton Fidler says a pillar-strength cannot be an absolute quantity, but may be anywhere between Euler and Gordon's results."

The theory of heat engines is treated in an equally scrappy and inconclusive fashion. The student will not find it easy to reconcile what he is told on p. 609 as to the efficiency of the engine not depending on the working substance, with the statement, on p. 613, that "in practice it is difficult to find a sufficiently perfect substance"—which is given as a reason why the efficiency of a real engine is less than the efficiency in Carnot's cycle. He will find himself also at a loss to understand the statement that "in adiabatic expansion external work is done at the expense of internal heat, and is therefore negative"; or to see why the dryness fraction of steam is necessarily "a whole number" (p. 594). Again, to take a matter of first-rate importance in regard to the action of steam in the cylinder, initial condensation is spoken of as if it affected the efficiency merely by the trifling alteration it produces in the form of the expansion curve, and we do not find a hint as to the real reason for its highly prejudicial effect.

It would be unfair to conclude that all the theoretical portions of the book are equally unsatisfactory. But at the best, their brevity, and the narrow limits of mathematical knowledge which the author assumes on the part of his readers, make this part of the work more like an engineering pocket-book than a treatise, the purpose of which ought to be to educate the student to reason about the application of mechanical principles to engineering. If the book, in this aspect, is representative of the teaching which the new Polytechnics are giving, it suggests the inquiry whether what Lord Armstrong once called "the vague cry for technical education" has met with the best possible response. We have no sympathy with those who would exclude either engineer apprentices or any other workmen from the highest education they are capable of. But the question may fairly be asked whether a good deal of what is apparently taught, and taught for the express purpose of enabling pupils to pass a specified examination, is in any just sense education at all. The mental discipline which would be obtained by making a real study of problems such as are touched on in this book, would be of the highest value as an education to the engineer. But there is no royal road to the comprehension of elasticity and thermodynamics. If the young apprentices and working lads, who, much to their credit, flock to the new Polytechnics, will take the trouble to truly master any of these things, they will gain an intellectual possession which will make them better men, if not directly better workmen. We would be the last to set a bound to their aspiration, or to discourage the study of Euler and St. Venant. But as a preparation for any such task, they must first, let us say, learn what is the meaning of a differential coefficient. To offer them scraps of conclusions which have to be taken on trust, and "reasons" which can carry conviction to no one except perhaps a jaded examiner, is giving stones to children who presumably cry for bread. If this represents the "theoretical" side of technical education as the new technical schools understand it, or as examiners accept it, we are still some way from a satisfactory solution of the much-vexed problem. For a great deal of this does not usefully instruct, and does not effectually educate: it is, as we have said, either too much or not enough.

THE LAKE OF GENEVA.

Le Léman Monographie Limnologique. By F. A. Forel. Tome second. (Lausanne: F. Rouge, 1895.)

THE first volume of Prof. Forel's work on the Lake of Geneva appeared in 1892, and was reviewed in these pages (vol. xlvii. p. 5). It dealt chiefly with the physical history of the lake-basin, while the present one, containing parts 6–10 of the whole work, begins with "Hydraulics," or the currents, waves, *seiches*, and other deviations of the surface from the normal form of a fluid at rest. It passes on to thermal questions, such as the temperature at different depths, freezing of the surface, &c.; next to optical questions, such as the colour, occasional iridescence and other peculiarities of the water, and the phenomenon of the *Fata Morgana*; then to acoustics (briefly); and lastly, to the chemistry of the water.

As it is impossible, in the limits of a comparatively short notice, to deal with the numerous subjects included in the present volume, we shall restrict ourselves to those which, perhaps, may be more widely interesting than the rest. The first one concerns those curious oscillations of the level of the lake, which locally are called *seiches*. This phenomenon, as defined by Prof. Forel, consists in an alternate rise and fall of the surface of the water; the movement being roughly comparable with that of a balanced plank, when set swinging by a slight disturbance. These oscillations are more or less rapid; their amplitude varying much. Commonly it is only a very few inches; but it may amount, though rarely, to about six feet, the disturbance sometimes lasting for twenty or twenty-five minutes. The whole question is discussed by Prof. Forel in its various aspects, and a history given of the different explanations which have been advanced. He attributes it neither to the effect of storms, nor to that of wind, nor to that of varying atmospheric pressure, but to a disturbance of the whole mass of water by earth-tremors, and compares it to the effect which may be produced on a fluid contained in a flat dish by tapping the bottom. In this hypothesis, however, he frankly admits the existence of a difficulty; namely, that earthquakes and

seiches are not always associated, for in some cases the former have not been accompanied by the latter. The difficulty is undoubtedly a serious one, and it is thus met by Prof. Forel. In an earthquake the undulatory movement is variable in character. In some cases it affects a pendulum seismograph, in others it does not; much depending on the rate at which the shock travels. If this be quick, it will not produce a perceptible undulation to a mass of water; if it be slow, it will set up a very sensible movement. Thus an earthquake of the latter type will produce a *seiche*, but not one of the former. There is much to be said in favour of this hypothesis; but further seismographic observations are required to show that there is a real coincidence between the nature of the earthquakes and the occurrence of the *seiches*.

More than one point of interest is discussed in the section dealing with optical questions. The Swiss lakes, as is well known, vary in colour, some having a distinctly green tint, but others, and especially the Lake of Geneva, being noted for the exquisite blue of the water. To facilitate comparative observation, Prof. Forel has constructed a scale of colours, beginning with sulphate of copper, as the pure blue, and representing the effects of chromate of potash added in proportions commencing with 2 and ending with 65 per cent. After a careful study of the whole question, he comes to the conculsion that the colour of the water depends not merely on the quantity of minute mineral matter present in a state of suspension, but also on the amount present in solution.

The third point, the chemistry of the water, is also very interesting. The author has collected together a large number of analyses already published, has added some others, and discusses the whole. These exhibit differences more considerable than we might have expected; for instance, the residue after evaporation varies from 160 to 218 mgs. per litre. These differences, allowing for possible errors, are probably due primarily to the affluents of the lake, the waters of which are long in becoming completely mixed with the main mass. The principal constituents of this residue are carbonate of lime, sulphate of lime, and carbonate of magnesia, the amounts being variable. Evidently they depend partly upon the time of the year, for in two samples, drawn from the same locality in January and in May, the numbers in the one case were as 3·3 : 2·6 : 1, in the other 3·7 : 1·4 : 1.

The volume, in short, is full of valuable matter, and worthy of its predecessor. As we said of that, it is a little too diffuse for a scientific treatise, but it was necessary, as the author then explained, to write it so as to attract a larger circle of purchasers.

T. G. BONNEY.

OUR BOOK SHELF.

A Catalogue of the Books and Pamphlets in the Library of the Manchester Museum. By W. E. Hoyle, M.A., F.R.S.E., Keeper of the Museum. (Manchester: J. E. Cornish, 1895.)

THIS catalogue, of 292 pp., owes its appearance in print to private enterprise, and is noteworthy as being classified according to the "Dewey Decimal System," under which each digit composing the registration number of a book marks a distinct narrowing in its significance, and for the arrangement under each class by Cutter's "Decimal Author Table," whereby each book receives a number which is virtually an abbreviation of its author's name. Thus, that "597·0941 Ya 21" denote the second, and "597·0941 Ya 2" the original edition of Yarrell's "History of British Fishes," may appear perplexing; but it is claimed by the advocates of the Dewey-Cutter systems that however much the library may grow, these numerical combinations will remain, and that they allow for maximum extension with minimum disturbance.

The classified catalogue upon which we have commented covers 230 pp., and is followed by a supplementary "author catalogue." The author modestly remarks in his preface, that the volume is "the work of one who is not a professional librarian." The labour of compilation has been great; and this catalogue, like all else that its author has put before the world, bears strongly the stamp of thoroughness and accuracy. We cordially recommend it to our university and public librarians, not, however, without a fear that they may adjudge it dangerous in its over-elaboration.

An index of subjects is appended, and Russian names have been transliterated according to the system advocated in our pages (NATURE, vol. xli. p. 396), and adopted in many of the principal scientific libraries.

A Course of Elementary Practical Bacteriology, including Bacteriological Analysis and Chemistry. By A. A. Kanthack, M.D., and J. H. Drysdale, M.B. (London: Macmillan, 1895.)

A LITTLE volume of 127 pages, primarily intended to carry candidates for diplomas in Public Health through a three months' course in bacteriology, and not pretending to be more than a laboratory guide. The instructions are extremely brief, and for the most part unaccompanied by any theoretical explanation. This entire divorce of theory and practice is, in our opinion, not unattended with danger, often leading the student to unintelligently cram the details of methods without having any proper understanding of the principles involved. It is frequently forgotten that the chief object of laboratory work should be to gain a living knowledge of a science, rather than the acquisition of mere dexterity in its practical technique. The exercises are, as we should anticipate from the experience and standing of the authors, well chosen, thoroughly representative, and cover a large amount of ground. On the other hand, some statements made without qualification may easily give rise to mistakes if accepted without reserve. Thus we are told that it is often possible to give a definite opinion in from eighteen to forty-eight hours, as to the presence or absence of cholera vibrios. Recent researches, however, go more and more to show that it is by no means so easy as was supposed to give a correct "definite opinion" as to the identity of this or any other particular micro-organism. We doubt whether bacteriology is sufficiently advanced to admit of treatment in quite such a final and hard and fast manner as it receives in this text-book; but we are told that these pages are not to supplant the demonstrator, and we would add that they should be carefully supplemented by the teacher. If thus employed, this work should prove a very valuable addition to the bacteriological literature of our country. Especially welcome is the inclusion of the principal methods for the detection of some of the chemical products of bacterial life.

Primer of Navigation. By A. T. Flagg. (London: Macmillan, 1894.)

MR. FLAGG'S little primer can be strongly recommended to all beginners; it is the A B C of the art of navigation. Every step is explained in the most simple and accurate manner; and for students depending upon self-instruction, a better or more clearly written primer would be difficult to imagine.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Origin of the Cultivated Cineraria.

AFTER reading the recent letters on the origin of the cultivated Cineraria, I have consulted the principal authorities cited by Mr. Bateson in NATURE of April 25: I now wish to point out that Mr. Bateson has omitted from his account of these records some passages which materially weaken his case.

Mr. Bateson, as I understand him, considers his letter to prove (1) that modern Cinerarias arose as hybrids from several distinct species; and (2) that the main features of existing varieties were established between about 1830 and about 1846, as a result of the appearance of considerable "sports" among these hybrids or their offspring. I will first discuss the latter half of the letter, in which authorities are quoted to prove two special acts of hybridisation, performed at known dates by known persons, and to show that certain named varieties arose as "sports."

First, as to hybridism. Drummond, of Cork, writing in 1827, is quoted as recommending the cultivation of *C. cruenta* for the production of "fine double and single varieties of different colours." At this date, therefore, *C. cruenta* was apparently variable, and yielded forms worth cultivation without hybridisation.

An article by Mrs. Loudon, written in 1842, is next quoted as evidence that "in or about 1827" Drummond obtained "some handsome hybrids" between *C. cruenta* and *C. lanata*. In this article a list of other hybrids, said to have been produced by unnamed persons between 1827 and 1842, is also given. It is not stated that these hybrids were grown by florists for exhibition, or that they had received definite names. The list is followed by a paragraph, omitted by Mr. Bateson, which is so important that I copy it at length:

"Some of the most beautiful Cinerarias now in our greenhouses have been raised by Messrs. Henderson, Pine-Apple Place; particularly *C. Hendersonii* and the King, both raised from seeds of *C. cruenta*. *C. waterhousiana* was raised by Mr. Tate, gardener to John Waterhouse, Esq., of Well Head, near Halifax, from seed of *C. Tussilaginis*, fertilised by the pollen of *C. cruenta*. Two new ones have lately been raised, of remarkably clear and brilliant colours, apparently from *C. cruenta*, named Queen Victoria and Prince Albert, by Mr. Pierce, nurseryman, of Yeovil, Somersetshire." (*Ladies' Magazine of Gardening*, 1842, p. 112.)

This passage clearly shows that in the writer's belief the hybrids produced by Drummond and others had not given rise to two, at least, of the named varieties of her time: certainly two, and probably two more, were descended from *C. cruenta* alone.

Mr. Bateson refers to this account of *C. waterhousiana*, and also to an earlier one, said to be communicated by Tate himself, the originator of the plant, to a writer in *Paxton's Magazine of Botany*, for 1838. In this account the parents are called *C. cruenta* and *C. tussilagofolia*; and in this, the earliest account, there is no statement as to which species furnished seed and which pollen. I do not know whether *Tussilagofolia* was ever recognised as a synonym of *C. Tussilaginis* or not; since the name does not occur in the *Index Kewensis*, where I find, as the only entry bearing on the subject, "*Waterhousiana* = *Senecio tussilaginis*?" Mr. Bateson has assumed that *Tussilagofolia* is identical with *Tussilaginis*, for while repeating only the statement given by Mrs. Loudon, he cites both her article and that in *Paxton's Magazine* as authorities. Is he sure that there did not exist in 1838 a florist's variety named *Tussilagofolia*?

Again, the writer in *Paxton's Magazine* goes on to express an opinion, not referred to by Mr. Bateson, that several of the florist's varieties known to him are descended from *C. cruenta* alone. He recommends the cultivation of various "species and varieties" (*not* hybrids) of Cineraria, and says "one species especially merits cultivation, namely *C. cruenta*. This may be regarded as the parent of many of those beautiful varieties which are so successfully cultivated by Messrs. Henderson." (*Paxton's Mag. Bot.* iv. p. 220, *not* p. 43.)

Against these specific statements, the only contemporary assertion that all named varieties are hybrids, which is quoted by Mr. Bateson, occurs in the *Journal d'Horticulture*, &c. (Ghent, 1846). This journal contains a general statement that florists' Cinerarias have been produced by crossing and recrossing several species, which are named; but although a list of florists' varieties is given, the exact history and parentage of each variety is not attempted.

Finally Burbidge, who wrote in 1877, is quoted as believing that existing varieties are due to hybridism between three species. It is not mentioned that Burbidge, before giving the systematic list of hybrid plants, in which the passage relied upon occurs, is careful to point out the uncertain nature of much of his evidence, and even writes, by way of caution to his readers, that "the parentage of many of the hybrids enumerated in this book is open to question" (p. 118).

I have only examined one of Mr. Bateson's cases of alleged "sports," namely *C. webberiana*. This plant, as Mr. Bateson says, is described and figured as having flowers of a deep blue, the rays being short and wide as compared with *C. waterhousiana*, for example. I fail to see why Mr. Bateson calls this a "sport." There is no evidence cited by him to show that it is descended from *C. waterhousiana*: and if it is not, then there is nothing remarkable in the shortness of its rays. The colour gives no evidence, without detailed knowledge of its descent; for I find in *Paxton's Magazine*, between 1838 and 1841, varieties recorded which are "lilac tipped with purple," "approaching to a blue," "bright blue," "blue or bluish," and in 1842 comes this "deep blue" variety *webberiana* to complete the gradual series.

Judging only from the documents referred to, it seems clear (1) that *C. cruenta* was cultivated, in what was believed to be a pure state, in 1827, and that it yielded valuable varieties, single and double, at that date; (2) that according to contemporary opinion, many of the varieties cultivated between 1838 and 1842 were directly descended from *C. cruenta*, and were not hybrids; and (3) that in 1842 some florists, at least, were believed to produce new varieties by the continued cultivation of *C. cruenta* alone.

So far as Mr. Bateson's history goes, therefore, it establishes the existence in 1842 of sufficient named varieties, believed to be pure-bred *C. cruenta*, to serve as parents for the flowers of to-day.

As to the actual pedigree of the modern varieties, I am not qualified to express an opinion. All I wish to show is that the documents relied upon by Mr. Bateson do not demonstrate the correctness of his views: and that his emphatic statements are simply evidence of want of care in consulting and quoting the authorities referred to.

W. F. R. WELDON.

University College, London, May 13.

I HAVE read with some interest the communications on this subject which have appeared in NATURE, and I may add that I have examined living plants of the species in question with Mr. Thiselton-Dyer. My memory also serves me sufficiently far back to remember a great variety of different "strains" of *Cineraria*, in which they had not got so far away from the parent *C. cruenta* as they now are. I say the parent *C. cruenta*, because I believe that we have to deal with races or strains, obtained by selection according to the taste of the several selectors, and not with the descendants of hybrids between different species. I think Mr. Bateson has relied too implicitly on the literature of the subject. Many of the records of hybrid productions in the vegetable kingdom are based upon groundless assumptions; mere seminal variations having been mistaken for crosses. It requires some skill and care to raise hybrids in the Compositæ; and when you have raised your hybrid, even assuming a fertile one, you can only propagate it vegetatively. All stability is gone. But it is not so with selected seminal variations of a given species. They will intercross most freely, and give birth to new varieties without end; yet each one of those varieties may be reproduced from seed, by careful isolation, without a single "bastard" appearing. There are several instances among our cultivated plants of this great plasticity combined with stability, but I will give only one—the China Aster. I select this because there can be no question of hybridity; and there is as great, or even a greater, variety than in the herbaceous Cinerarias. But with regard to the latter, I think our experience and the trustworthy literature go to prove that it is an analogous case. Careful selection, year after year, has resulted in the various fixed races or strains offered by florists. I am aware that the letters

on this subject by no means exhaust it; but I think it may be safely asserted that selection has yielded much more than sports.

W. BOTTING HEMSLEY.

Prof. Milne's Observation of the Argentine Earthquake, October 27, 1894.

A FEW days ago I received from Prof. Milne a letter, dated March 15, 1895, in which he sends me a list of earthquake disturbances, compiled from the records he was fortunate enough to rescue from the fire which destroyed his house on February 17. In this list I find no less than three observations of the great Argentine earthquake of October 27, 1894, which was recorded by three different horizontal pendulums. The times given for the beginning of the earthquake—viz. 18h. 0m., 18h. 5m., 17h. 41m.[1]—are not very trustworthy, because they were determined by measuring the linear distance from a break in the curve which was caused regularly every day about noon by taking away the lamp. The exact times of these breaks were noted in a book, which, unfortunately, was destroyed by the fire. Prof. Milne, however, tells me that in the instrument, to which corresponds the first of the above-mentioned times, the lamp was always removed within half a minute or one minute from noon (Japan time). Consequently, the error cannot exceed a few minutes. The duration of the disturbance was between two and three hours in all the three instruments.

If we consider that the error of the first observation is not likely to exceed ten minutes, then we find, by comparing Prof. Milne's observations with those made in Europe, that although the spherical distance between the epicentre of the earthquake and Tokio is *no less than* 17,400 *kilometres*, the earth-motion reached Japan at about the same time, or perhaps even a little earlier, than it arrived in Europe. It is unnecessary to point out the interest which is attached to systematic observations of this kind. Prof. Milne's observation is probably the first in which an earthquake was noticed by seismic instruments at a place so near the antipodes of the earthquake centre. A straight line between the two points is only very little shorter than the earth's diameter; the time required for the motion to pass through the globe was probably less than twenty minutes.

Merseburg, May 1. E. VON REBEUR-PASCHWITZ.

Guanine in Fishes' Skins.

IN a joint paper by Mr. J. T. Cunningham and myself (*Phil. Trans.* vol. clxxxiv., 1893, B, pp. 765–812), we have ventured to question the accuracy of the statement made in many text-books of physiological chemistry, that guanine occurs in combination with calcium in the skin of fishes. We found that the guanine occurs in the free state. In the last number of Hoppe-Seyler's *Zeitschrift für Physiologische Chemie* there is a paper by Herr Albrecht Berthe, dealing with this subject, in which he shows that the calcium so frequently found with the guanine is due to the presence of impurities derived from the tissues and the scales. Its amount depends upon that of the impurities present, and is very variable. Instead of finding 11·76 per cent. required by the formula of "*Guaninkalk*," Berthe finds less than one-third of that percentage present, and even this also varies within wide limits. In the paper referred to above, we found one source of the calcium was due to the presence of comparatively large crystals of calcium phosphate, which are figured on p. 788; but there is no doubt that the bulk of it is derived from the scales.

Oakleigh, Wolverhampton, May 4.

The Oldest Vertebrate Fossil.

NOTICING in your issue of April 11 a reference to the discovery of specimens of *Cyathaspis* in the Silurian of Gotland in strata equivalent to the English Wenlock, and with it the statement that these fossils are "for the present the oldest known vertebrates," I am led to call your attention to the species described by myself from Silurian strata in Pennsylvania in 1885 (p. 48), and again in 1892 (p. 542), in the *Quarterly Journal* of the Geological Society. I forward with this a copy of the paper, from which it will be seen that the Salina (Ononduga) beds that yielded *Palæaspis* are older than the Ludlow (or Lower Helderberg), and that the Clinton are older than the Wenlock (or *Niagara*). Consequently *Onchus Clintoni* of the latter group is thus far the oldest vertebrate. E. W. CLAYPOLE.

Akron, Ohio.

[1] These hours are Japan time, *i.e.* 9h. east of Greenwich, and are reckoned from noon.

TERRESTRIAL HELIUM.

SINCE our last reference to this subject three communications have been laid before the Royal Society. They are as follows:—

HELIUM, A GASEOUS CONSTITUENT OF CERTAIN MINERALS.[1]

An account is given of the extraction of a mixture of hydrogen and helium from a felspathic rock containing the mineral clèveite. It is shown that in all probability the gas described in the preliminary note of March 26 was contaminated with atmospheric argon. The gas now obtained consists of hydrogen, probably derived from some free metal in the felspar, some nitrogen and helium. The density of helium, nearly free from nitrogen, was found to be 3·89. From the wave-length of sound in the gas, from which the theoretical ratio of specific heats 1·66 is approximately obtained, the conclusion may be drawn that helium, like argon, is monatomic. Evidence is produced that the gas evolved from clèveite is not a hydride, and a comparison is made of the spectra of argon and helium. There are four specially characteristic lines in the helium spectrum which are absent from that of argon: they are a brilliant red, the D_3 line of a very brilliant yellow, a peacock-green line, and a brilliant violet line. One curious fact is that the gas from clèveite, freed from all impurities removable by sparking with oxygen in presence of caustic potash, besides other fainter lines, exhibits one, and only one, of the characteristic bright red pair of argon lines. This, and other evidence of the same kind, appears to suggest that atmospheric argon and helium have some common constituent.

Attention is drawn to the fact that on subtracting 16 (the common difference between the atomic weights of elements of the first and second series) from 20, the approximate density of argon, the remainder is 4, a number closely approximating to the density of helium; or, if 32 be subtracted from 40, the atomic weight of argon if it be a monatomic gas, the remainder is 8, or twice the density of helium, and its atomic weight if it too is a monatomic gas.

ON THE NEW GAS OBTAINED FROM URANINITE.[2]

Since my communication on the gas obtained from Uraninite (Broggerite) was sent in to the Society on the 25th ult., I have been employing the method I there referred to in several directions, among them to determine whether the spectrum of the gas indicates a simple or a complex origin.

I was led to make this special inquiry on account of the difference in the frequency of the appearance of D_3 and the other lines to which I referred in the solar chromosphere. For instance, if we take the lines D_3, 4471, and 4302, the frequencies are as follows, according to Young[3]:—

D_3	100	(maximum)
4471	100	,,
4302	3	

Hence, we might be justified in supposing that D_3 and 4471 are produced by the same gas, and that 4302 owes its origin to a different one.

But further experiment has given me one case in which D_3 shows bright, while 4471 is entirely absent. I may now add that an equally important line to 4471, one at 4026·5, appears, with the dispersion employed, in the spectrum of Bröggerite, and both these lines are wide and fluffy, like the lines of hydrogen, and are apparently reversed.

The line 4026·5 has not been recorded by Young, though, as I have stated, the frequency of appearances of 4471 represents the maximum; still, while this is so, the intensity of both these lines in the spectra of the hottest stars is not surpassed, even by those of hydrogen. Hence, opinion as to their representing the same gas must be suspended. Further, I have photographed a line at 4388 apparently coincident with another important line in the same stars. Whether, coming from one source or two, in these three lines seen along with D_3 in the gas obtained by me from Bröggerite, we have, it would seem, run home the most important lines in the spectra of stars of Group III., in which stars alone we find D_3 reversed. Should these results be confirmed, the importance of the gas or gases they represent at a

[1] By Prof. W. Ramsay, F.R.S. (abstract).
[2] Second note. By J. Norman Lockyer, C.B., F.R.S.
[3] See "Solar Physics," Lockyer, p. 612.

certain stage of the evolution of suns and planets can be gathered from an examination of a photograph of the spectrum of Bellatrix.

Another case is afforded by a line at λ 667. This is associated with D_3 in Bröggerite and Cleveite, but the yellow line has been seen in Monazite *without* λ 667. It is almost certain, then, that these two lines represent two gases. Certainty cannot be arrived at till a larger quantity of gas has been obtained.

Again, the red line at λ 6575, close to C, referred to in my previous communication, is seen both in Gummite and Broggerite; but in one case (Gummite) it is seen without D_3, and in the other with it, in one case (Bröggerite) without λ 614, and in the other with it. The above conclusions hold here also.

This line λ 614, possibly coincident with a chromospheric line, has been recorded in Gummite and Broggerite. It has been seen *with* D_3 (in Broggerite) and *without* it (in Gummite).

I have said enough to indicate that the preliminary reconnaissance suggests that the gas obtained from Bröggerite by my method is one of complex origin.

I now proceed to show that the same conclusion holds good for the gases obtained by Profs. Ramsay and Cleve from Cleveite.

For this purpose, as the final measures of the lines of the gas as obtained from Cleveite by Profs. Ramsay and Cleve have not yet been published, I take those given by Crookes,[1] and Cleve,[2] as observed by Thalén.

These are as follows, omitting the yellow line:—

Crookes.	Thalén.
	6677
568.05	
566·41	
516·12	
	5048
	5016
500·81	
	4922
480·63	
	4713·5

The most definite and striking result so far obtained is that, in the spectra of the minerals giving the yellow line, I have so far examined, I have never once seen the lines recorded by Crookes and Thalén in the blue. This demonstrates that the gas obtained from certain specimens of Cleveite by chemical methods is vastly different from that obtained by my method from certain specimens of Broggerite; and since, from the point of view of the blue lines, the spectrum of the gas obtained from Cleveite is more complex than that of Broggerite, the gas itself cannot be more simple.

Even the blue lines themselves, instead of appearing *en bloc*, vary enormously in the sun, the appearances being-

4922 (4921·3) = 30 times
4713 (4712·5) = twice.

These are not the only facts which can be adduced to suggest that the gas from Cleveite is as complex as that from Bröggerite. But while, on the one hand, the simple nature of the gases obtained by Profs. Ramsay and Cleve and by myself must be given up, reasoning on spectroscopic lines; the observations I have already made on several minerals indicate that the gases composing the mixtures are by no means the only ones we may hope to obtain.

This part of the inquiry will be more specially considered in a subsequent communication.

I may remark in conclusion that in this preliminary inquiry no attempt has been made to separate the possibly new gases from the known ones which come over with them; hence, the lines are in some cases very dim, and the application of high dispersion is impossible. The wave-lengths, therefore, especially in the visible spectrum, are approximations only; but the view that we are really dealing with gases operative in the solar atmosphere, like the helium which produces D_3, is strengthened by the fact that of the 60 lines so far recorded as new in the various minerals examined, about half occur near the wave-lengths assigned to chromospheric lines in Young's table. I am aware that most of the chromospheric lines have been recently referred to as due to iron, but I believe this result does not depend upon direct comparisons, and it is entirely opposed to the conclusions to be drawn from the work of the Italian observers, as well as from my own.

[1] NATURE, vol. li. p. 544.
[2] *Comptes rendus*, April 16, p. 835.

ON THE NEW GAS OBTAINED FROM URANINITE.[1]

In my preliminary note communicated to the Royal Society on the 25th ult. I gave the wave-lengths of the lines which had been observed both at reduced and at atmospheric pressure in the gas (or gases) produced by the method to which I then referred of heating the mineral Uraninite (Bröggerite) in vacuo.

As a short title, in future I shall term this the distillation method.

Since then the various photographs obtained have been reduced and the wave-lengths of the lines in the structure spectra of hydrogen observed beyond the region mapped by Hasselberg.

I have further observed the spectra of other minerals besides Uraninite for the purpose of determining whether any of them gave lines indicating the presence of the gas in Uraninite or of other gases.

I now give a table of the lines so far measured in the spectra of 18 minerals between λλ 3889 and 4580 R, the region in which, with the plates employed, the photographic action is most intense.

Lines Photographed in the Spectra of Gases obtained from various Minerals experimented upon up to May 6.

Wave-length. Rowland.	Wave-length. Ångström.	Chromospheric lines (Ångström's scale.)	Eclipse lines (1893), Rowland's scale (1893).	Orion star lines (Rowland's scale).	Remarks.
3889	3888·5	3888·73 H.	3889·1	*	U
3947	3946·5	3945·2 H.	3946·0		U
3982	3981·5		3982·0		
4026·5	4025·9		4026·5	4026·5	U
4142	4141·3				
4145	4144·3		4144·0	4144·0	
4177	4176·3	4178·8	4177·8	4178·0	
4182	4181·3				
4338	4337·3	4338	*	4338·0	
4347	4346·3			4346·0	
4390	4389·3	4388·5	4390	4389·0	
4398	4397·3	4398·5	4398·7		
4453	4452·3		4454		
4471	4470·3	4471·2	4471·8	4471·8	U
4515	4514·3	4514·0	4514·5		
4522	4521·3	4522·0	4522·9		
4580	4579·3				

* Broad hydrogen lines extend over these positions.
U = lines noted frequently in the spectra of Bröggerite.
H = photographed by Hale.

On this table I may remark that, of the lines given in my paper of April 25, the final discussion has shown that the following lines are hydrogen structure lines in the region beyond that mapped by Hasselberg:—

λλ 4479, 4196, 4156, and 4152·5.

The line 4368 is also omitted from this list, as it has not been finally determined whether it coincides with a line of O.

In the table, besides the λλ on Ångstrom's and Rowland's scale, I give lines which have been observed in the sun's chromosphere and chronicled by Young; those photographed during the eclipse of 1893 with a 6-inch prismatic camera, by Mr. Fowler, and those photographed with the same instrument at Kensington in some stars of Group III. of my classification in the constellation of Orion.

This table carries the matter of the relation of the new gases to star and stellar phenomena much further than I ventured to suggest in my second note.

We appear to be in presence of the *vera causa*, not of two or three, but of many of the lines which, so far, have been classed as "unknown" by students both of solar and stellar chemistry: and if this be confirmed, we are evidently in the presence of a new order of gases of the highest importance to celestial chemistry, though perhaps they may be of small practical value to chemists, because their compounds and associated elements are, for the most part, hidden deep in the earth's interior.

The facts that all the old terrestrial gases, with the exception

[1] Third Note. By J. Norman Lockyer, C.B., F.R.S.

of hydrogen, are spectroscopically invisible in the sun and stars—though they doubtless exist there—and that these new gases scarcely yet glimpsed, have already, in all probability, supplied us with many points of contact between our own planet and the hottest part of our central luminary that we can get at, and stars like Bellatrix, are full of hope for the future, not only in relation to the possibility of more closely correlating celestial and terrestrial phenomena, but in indicating that a terrestrial chemistry founded on low density surface products in which non-solar gases largely enter, is capable of almost infinite expansion when the actions and reactions of the new order of gases, almost, it may be said, of paramount importance in certain stages of stellar evolution, shall have been completely studied.

With regard to the differences indicated between the results of the chromospheric and eclipse observations in the above table, it may be useful to remark that Prof. Young's "frequencies," invaluable though they are, must necessarily be of less importance, from the present point of view, than the eclipse observations obtained, it may almost be said, at the same instant of time. There may be, and doubtless are, two perfectly distinct causes for the appearance of the so-called chromospheric lines. First, the tranquil condition of the lower strata of the sun's atmosphere which gives us the pure spectrum produced at a constant—and the highest that we know of in the sun—temperature. Secondly, the disturbed condition which fills the spectrum with lines of a so-called prominence. Formerly it was universally imagined that the prominences were shot up from below; and in that case the lines added would indicate a temperature *higher* than the normal. But I have sent many papers in to the Society indicating the many arguments against this view,[1] and to me, at the present time, this view is almost unthinkable. If these disturbance-lines are produced from above, they may represent the effects of many stages of *lower* temperature. Hence a list of chromospheric lines loses most of its value unless the conditions of each observation are stated, and the phenomena appearing at the same place at the same instant of time are recorded.

Now, this same place and same time condition is perfectly met by eclipse photographs, and hence I attach a great value to them. But the comparison between such eclipse observations and the spectra of certain stars indicates that the latter in all probability afford the best criteria of all.

[1] They are set out at length in the "Chemistry of the Sun," which I published in 1887.

THE MARQUIS OF SAPORTA.

IN the study of palæobotany we may concern ourselves with the various problems of distribution, the geologic sequence of plant types, the value of fossil plants in comparative stratigraphy, and as tests of climatic conditions; or our attention may be concentrated on the important facts revealed by a microscopic study of petrified plant tissues. The latter field of research, in which Prof. Williamson has laboured with remarkable success during the last twenty-five years, is gradually being recognised by botanists as a branch of their science which they cannot afford to neglect in dealing with the wider problems of plant life. Fascinated by the almost incredible perfection in which Palæozoic, and more rarely Mesozoic, species have been preserved, the student of vegetable morphology is apt to take too little heed of the wealth of material which can only be studied in the form of structureless casts or impressions. In the majority of fossil floras the geologist or botanist must perforce confine himself to an examination of the few isolated and imperfect fragments that have escaped destruction in the process of denudation and rock-building, and have been preserved by fossilisation as meagre representatives of a past vegetation. As a specialist in this latter branch of palæobotany, there has been no more ardent worker since the days of Adolphe Brongniart, whom we may regard as the founder of palæobotanical science, than the Marquis of Saporta. Saporta's recent death, at his home in Aix-en-Provence, at the age of seventy-two, has deprived botanical and geological science of an unusually able and vigorous worker.

A perusal of Saporta's numerous contributions to scientific literature affords abundant evidence of critical and detailed investigation during a long period of years; nearly the whole of his published work has been in the domain of fossil botany. The Tertiary vegetation of France forms the subject of several of his contributions to science. From an early stage of his career the Cainozoic plant-bearing strata of Provence have occupied a prominent position in his palæobotanical studies: the Eocene flora of Aix, a valuable monograph on the remnants of an Eocene flora preserved in the tuffs of Sézanne, and various other writings on Tertiary plants, bear eloquent testimony not only to a remarkable power of detailed systematic work, but to a striking aptitude for a broad and philosophic manner of treatment. Students of Mesozoic botany soon learn to appreciate Saporta's memoirs on Cretaceous and Jurassic plants, and especially the splendid series of monographs on the Jurassic flora of France, published as separate volumes of the "Paléontologie Française" from 1873-91; in this profusely illustrated work, dealing primarily with French vegetation, we have to a large extent a general handbook of Oolitic botany. One feature which sets a high value on Saporta's palæobotanical work, is his wide and thorough acquaintance with the facts of distribution and taxonomy of living plants. Palæontological records are often in themselves of no special interest to zoologists and botanists, but if interpreted as indices of plant distribution in past ages, and applied to the wider problems of the evolution and dissemination of plant types, they assume considerable importance. Saporta's knowledge of recent floras, and his keen enthusiasm as an evolutionist, led him to regard fossil plants not simply as convenient aids to the stratigraphical geologist, but as affording indispensable data to the student of plant phylogeny. In "Le Monde des plantes avant l'apparition de l'homme" (Paris, 1879), we have a series of articles originally published in the *Revue des Deux Mondes* and *La Nature*, in which Saporta's encyclopædic information and finished literary style combine to render attractive to the layman and the specialist a retrospect of plant life during the geologic ages. Unfortunately the elaborate frontispiece to this volume, described as the "oldest known land plant," and named *Eopteris Morierei*, is merely a representation of an iron pyrites infiltration on the surface of a Silurian slate, and cannot be retained as a plant impression. In a more recent and smaller volume, "Origine paléontologique des arbres cultivés ou utilisés par l'homme" (Paris, 1888), we have an interesting sketch of the geological history of existing forest trees; and in another and more ambitious work,[1] in collaboration with Prof. Marion, an attempt is made to follow the lines of descent of the several subdivisions of the vegetable kingdom. The palæobotanist who is bold enough to venture on the task of tracing out the ancestry of plant forms, and of attacking the problems of development, is exposed to the very serious danger of allowing unsound links to form part of his chains of life. Saporta's constant desire to treat fossil plants from the point of view of a sanguine evolutionist, who wishes to press into his service all possible pieces of evidence towards the better understanding of the process of plant evolution, has in certain instances been led beyond the limits of accurate scientific reasoning. The majority of the so-called fossil algæ, to which he has devoted considerable attention, have been put out of court by Nathorst and others, as having no claim to consideration as records of thallophytic life; and it is generally agreed that the value of his work in this direction is seriously discounted, by the more than doubtful specimens which are described as vestiges of the lower and more primitive forms of plants. A few months before his death, Saporta completed an exhaustive monograph on

[1] Saporta and Marion: "L'évolution du règne végétal." 3 vols. 1881-1885.

the Mesozoic flora of Portugal;[1] this work marks an important advance in our knowledge of Lower Cretaceous and Upper Jurassic vegetation; and of special interest are the various forms of "archetypal angiosperms" closely resembling similar fossils from the Potomac beds of North America. This last monograph, full of elaborate botanical and stratigraphical work, affords a striking proof of the energy and youthful enthusiasm of the veteran student. Saporta's name will ever be held in respect by succeeding generations as that of a pioneer of palæobotanical science; and by those who were privileged to know him personally, or as a correspondent ever ready to render assistance to younger workers, the death of the Marquis of Saporta must be felt not merely as the termination of the labours of one of the foremost palæobotanists, but as the removal of a generous friend and colleague, whose wide knowledge and untiring devotion to science will stimulate younger investigators to more vigorous efforts in the rich field of palæobotanical study.

A. C. Seward.

SIR GEORGE BUCHANAN.

The death of Sir George Buchanan removes from our midst a leader in that branch of medical science which concerns itself with the prevention of disease. His death came very unexpectedly, for the circumstances of his ill-health were known only to a circle of intimate friends; and his great desire to go on working as long as work was practicable, made him sufficiently cheerful to disguise the suffering which he at times experienced. It is some three years since he resigned the post of medical officer to the Local Government Board, this step having been taken by him on account of failing health. But he still found plenty of pleasurable occupation in connection with the various learned and scientific bodies with which he was associated, and he also served on the Royal Commission on Tuberculosis, of which he became chairman on Lord Basing's death. He was a pupil of University College, of which body he became a Fellow; he graduated B.A. and M.D. at the University of London, and at his second M.B. he distinguished himself by carrying off several gold medals and scholarships. Later on he became medical officer of health to the district of St. Giles, where he laboured hard for years to improve the conditions of public health and to amend the then terribly faulty circumstances under which the people lived. It was here that he attracted the attention of Sir John Simon, then medical officer of the Privy Council, and under him he served both as a temporary and, later on, as a permanent medical inspector. During this period, and subsequently when he himself directed the public health department of the State, the investigations which he carried out, and the reports which he presented to Parliament, embodied the results of work of which England may feel proud. As a type of the class of work we refer to, we may instance his prolonged investigations into the influence on health of large public works, of water-supply and sewerage, and his discovery of the lessening of mortality from pulmonary consumption wherever the construction of sewers had led to a lowering of the sub-soil water. Some of his papers on the subject of vaccination in relation to small-pox are also of the greatest value; they were the result of most careful labour, as well as of an earnest desire to eliminate all possible sources of error, and to arrive at the truth alone; and the more he studied the subject, the more convinced he became of the value of vaccination as a measure of public health. He sought to secure for all the work he did or supervised a truly scientific basis; and he always attached the greatest importance to the auxiliary scientific work for which a special, but only a small, grant is annually made to the medical department of the Local Government Board. He had a marked literary talent, and a conspicuous power of setting out the salient points of the work done by his inspectorial staff; with the result that his annual reports have gradually come into great demand by sanitarians and public health authorities in almost every part of the world. The result of all his labours is by no means accomplished, in some places work on the lines he has indicated has hardly commenced, and it must almost necessarily be that much that he has taught, will, in the lapse of time, fail to be associated with his name. But those who know the nature of his work, and who appreciate the thoroughness which always characterised it, will readily understand how far-reaching and beneficial the results must in the end be. In 1882 he was elected to the Senate of the University of London, and in the same year he was made a Fellow of the Royal Society; but otherwise distinctions came to him mainly at the close of his official career. This was doubtless largely due to all absence of self-seeking in his character. As head of a department he was always trying to promote the welfare of those under him, and it was only when he retired on a comparatively small pension that he asked for some consideration in view of the long services he had rendered to the State before he gave his whole time to his official duties. But the Treasury gave their usual answer, and he said no more. At this date he was made a Knight Bachelor, and in 1893 he received the honorary degree of LL.D. of the University of Edinburgh. He was a past President of the Epidemiological Society, a Censor of the Royal College of Physicians of London, and he acted as adviser in scientific and other matters to several other bodies. If such a characteristic can be deemed a fault, Sir George Buchanan's most prominent failing was an inability to conceal his sense of those who, as he thought, sacrificed principles and, at times, the truth itself in matters relating to the advancement of public health, for purposes of notoriety or of policy. But, on the other hand, no chief of a public department ever won the affection as well as the esteem of his staff better than Sir George Buchanan did; and he made it no secret that in regard to this he was always desirous to recall the example of his own former chief, who, happily, still lives, and to whom he was devotedly attached.

[1] "Flore fossile du Portugal" (Direction des travaux géologiques du Portugal). [illegible]

NOTES.

Our readers will be glad to know that Prof. Huxley continues to improve in health. A telegram received from Eastbourne as we go to press states that he is progressing favourably, and is able to get up daily, but is hardly strong enough yet to leave his room.

The Bill, which was introduced into the House of Lords on Thursday last by Lord Playfair, on behalf of the Government, may be fairly said to bring the reconstruction of the University of London on the lines of the Gresham Commissioners' Report within the sphere of practical politics. The exact terms of the Bill have not yet transpired, but it is understood that the four Commissioners appointed to administer the Act are, in the first place, empowered to make modifications in the scheme if deemed expedient after consultation with the Senate and Convocation of the University of London, and other bodies affected; and in the second, enjoined to adequately safeguard the interests of the external or non-collegiate students. The Government having at last taken action on this question, it is the more satisfactory to note that the attempt made in Convocation on Tuesday last to rescind the resolutions passed at the January meeting (vol. li. p. 298), has completely failed, a resolution to the effect that "if a local Teaching University for London be desirable, it ought to be constituted apart from the existing University of London," being rejected by 238 against 117, or by a majority of 121 votes.

THE unveiling of a memorial tablet to the late Prof. J. C. Adams at Westminster Abbey, on Thursday last, was an event in which all men of science are interested. It might have been made a great occasion, for Adams' name is esteemed throughout the scientific world, instead of which the meeting seems chiefly to have represented the University of Cambridge. The tablet has been placed in the north aisle, close to the graves of Newton, Herschel, and Darwin. It is the work of Mr. Bruce Joy, and bears the following inscription :—"Johannes Couch Adams, Planetam Neptunum Calculo Monstravit. MDCCCXLV."

A BILL incorporating the New York Zoological Society, and providing for the establishment of a zoological garden in New York, has just been approved by Governor Morton. The Act provides that the corporation shall have power to establish and maintain in New York City a zoological garden for the purpose of encouraging and advancing the study of zoology, original researches in the same, and kindred subjects, and of furnishing instruction and recreation to the people.

ON April 26, the Linnean Society of Bordeaux held a meeting devoted to the question of bibliographical reform. The prospectus of the new Bibliographical Bureau for Zoology was approved by all the members present, and the wish was expressed that a similar organisation be at once attempted for the other branches of natural science. In accordance with this wish, it was decided to elaborate a project for the establishment of a Central Bureau for Botany. This project will be presented to the Association Française at its next meeting, by the President of the Botanical Section. M. Mourlan, the Director of the Académie des Sciences of Belgium, proposes similar action for geology. It is hoped that, by the establishment of several federated bureaus, the plan of the Royal Society may be fully realised and without great difficulty. Meantime, the organisation of the Zoological Bureau has made considerable progress, the circular of the French Commission has already appeared, and has been widely distributed by the French Zoological Society ; the American Commission has completed its preliminary study, and will soon send its circular to press. In other countries, notably in Russia, similar progress is reported.

THE programme of arrangements for the Ipswich meeting of the British Association has just been issued. The first general meeting will be held on Wednesday, September 11, when the Marquis of Salisbury will resign the chair, and Sir Douglas Galton, President elect, will assume the presidency, and deliver an address ; on Thursday evening, September 12, a soirée will be held ; on the following evening a discourse will be delivered by Prof. Silvanus P. Thompson on magnetism in rotation ; on Monday evening, September 16, there will be a discourse by Prof. Percy F. Frankland on the work of Pasteur and its various developments ; a second soirée will take place on Tuesday evening, September 17, and the concluding general meeting will be held on Wednesday, September 18. The Sections and their Presidents are as follows :—(*a*) Mathematical and Physical Science—President, Prof. W. M. Hicks, F.R.S. (*b*) Chemistry—President, Prof. R. Meldola, F.R.S. (*c*) Geology—President, W. Whitaker, F.R.S. (*d*) Zoology (including Animal Physiology)—President, Prof. W. A. Herdman, F.R.S. (*e*) Geography—President, H. J. Mackinder. (*f*) Economic Science and Statistics—President, L. L. Price. (*g*) Mechanical Science—President, Prof. L. F. Vernon Harcourt. (*h*) Anthropology—President, Prof. W. M. Flinders Petrie. (*k*) Botany—President, W. T. Thiselton-Dyer, C.M.G., F.R.S. Section I (Physiology) will not meet at Ipswich, but papers on animal physiology will be read in Section D. The delegates of corresponding Societies will meet on Thursday, September 12, and Tuesday, September 17, under the presidency of Mr. G. J. Symons, F.R.S. The acceptance of papers is, as far as possible, determined by organising committees for the several Sections, before the beginning of the meeting. It has, therefore, become necessary, in order to give an opportunity to the Committees of doing justice to the communications, that each author should forward his paper, together with an abstract, on or before August 12, to the General Secretaries of the Association.

SEVERAL summer schools for the practical study of botany will be held during the coming season in the United States—one in connection with Cornell University, and one in connection with the University of Wisconsin, both from July 8 to August 16 ; also one in connection with the Cambridge Botanical Supply Co., Cambridge, Mass., from July 5 for five weeks.

THE *Sitzungsberichte* of the Vienna Academy of Sciences (vol. civ.) contains a discussion of the observations of atmospherical electricity and St. Elmo's Fire on the Sonnblick by Messrs. J. Elster and H. Geitel, being a continuation of the observations to the time of the change of the former observer. The results confirm those previously obtained, and show that the yearly variation of the electrical energy at the summit is small, compared to that at the base, and that the summit of the mountain projects above those strata of the atmosphere in which electrical processes mostly occur. During the fall of fine snow the St. Elmo's Fire is mostly negative, but positive when large flakes of snow and hail are falling.

FROM a paper on early agriculture in Palestine, by Dr. H. Vogelstein, we learn the interesting fact that in the first two centuries of the Christian era, rainfall was measured by means of a receptacle. The Jewish *Mishnah* refers to two seasons, one wet and the other dry. In normal years the early rain fell soon after the autumnal equinox, and its importance to agriculture is frequently referred to in that document. The amount which fell at this season was about 21 inches, which agrees fairly well with the present measurements at Jerusalem, but the total annual fall is not stated by Dr. Vogelstein. Further particulars of this interesting communication will be found in the *Meteorologische Zeitschrift* for April.

PROF. L. H. BAILEY, of Cornell University, Ithaca, N.Y., has recently read before the Biological Society of Washington a paper entitled the "Plant-individual in the Light of Evolution." In this paper, according to the *American Naturalist*, he suggests the idea that both Lamarckism and Darwinism are true, the former finding its expression best in animals, the latter in plants. The plant is, according to him, not a simple autonomy, in the sense in which the animal is, and the parts of the plant are independent in respect to propagation, struggle for existence, and transmission of characters. According to this view there can be no localisation or continuity of germ-plasm in plants, in the sense in which these conceptions are applied to animals.

THE *El Universal* reports that the cold spell in February extended right down the Gulf of Mexico to Vera Cruz. On the 15th and 16th it was freezing over a distance of 80 leagues from Monterey to Ciudad Victoria and Tula in Tamaulipas, and the mountains were covered with snow. In the district of Tancanhuitz, State of San Luis Potosi, the sugar-canes and coffee-trees were all killed, the value of the coffee crop destroyed being estimated at a million dollars. In the Huasteca, State of Vera Cruz, sugar-canes, coffee, and tobacco were similarly killed—a loss of several million dollars—while cattle were dying by hundreds on the frost-bitten pasture lands. Owing to the frost having followed a prolonged drought, prices had risen to famine rates, and there was much sickness, especially croup and small-pox. In the district round Altotonga a very hot south wind set in on February 13, which suddenly cooled, and grew in intensity and cold. On the 14th, snow began to fall and did not cease till the 17th. Ten parishes in the temperate zone were snow-covere

for eighty-four hours, resulting in the destruction of all fruit, vegetables, coffee, and tobacco. The sugar-canes were so ruined as to be unfit even for forage. The twelve parishes of the district situated in the *terra fria* lost everything; the maize had not yet been planted, and would not be ripe till November or December. At Papantla, the vanilla centre, it was snowing on February 17, and the temperature had fallen from 30° C. to freezing point. At Misantla snow fell all night, and many fowls, animals, and cattle died from the cold.

Under the title, "Illustrations of Darwinism, and other Papers," Sir Walter L. Buller, F.R.S., has sent us a reprint of his presidential address to the Wellington Philosophical Society in 1894. Its main subject-matter is a discussion of the various ways in which the peculiarities of structure, colour, distribution and habits of New Zealand birds, serve to illustrate the theory of Natural Selection, and often to afford very strong arguments in its favour. The address is very clear and forcible, full of interesting facts and suggestive observations, and will be read with interest by all naturalists. One or two points only call for any critical observation. Sir W. Buller objects to the Apteryx being classed by Mr. Wallace as among "the lowest birds," because, he says, it is really "an extremely specialised form." But surely the Ratitæ are lower than the Carinatæ; and the Apteryx is specialised so as to be almost the least bird-like of the Ratitæ. If it is not to be classed among the lowest existing birds, where are these to be found? Again, the statement that the larger forms of animals have universally preceded the smaller in geological time (p. 101), is only a half-truth, if so much, since all these large forms have been developed from smaller ones, as shown in the case of the horse, as well as that of the early marsupials of the Meszoic period. Even more open to objection is the statement (p. 102), that the Siberian mammoth "would clearly have required a growth of tropical luxuriance to satisfy the wants of its capacious stomach"; and that its being found by thousands embedded in ice or frozen soil implies "a revolutionary change of climate." A sufficient answer to which theory is the fact that leaves and cones of firs have been found in the stomach, showing that it fed only a few degrees south of the places where it is now embedded.

A valuable addition to the various suggestions for the measurement of geological time is made by Dr. G. K. Gilbert in the *Journal of Geology* (vol. iii. No. 2). He has been struck with the regular, rhythmical cycles of sedimentation displayed over and over again by the shaly beds of the Cretaceous of Colorado (Benton, Niobrara, and Pierre groups). Such regularity, he suggests, can only be due to causal variations of a periodic character, and only astronomical changes have the regularity required. There seem to be only three astronomical cycles that can be reasonably appealed to for an explanation of rhythm in sedimentation: the periods of the earth's revolution around the sun, of the precession of the equinoxes, and of the variation in eccentricity of the earth's orbit. Dismissing the first as too short, and the last as too irregular, Prof. Gilbert considers there are three ways in which the second cycle might influence local sedimentation: (1) By periodic changes in winds, and therefore in marine currents; (2) by alternate glaciation of the two hemispheres, resulting in periodic advance and recession of coast-lines, and hence of sedimentation-boundaries; (3) alternation in terrestrial climate of moist periods—when, through the abundance of vegetation, chemical denudation would be at a maximum, and mechanical at a minimum—and dry periods, when the reverse would be the case. Assuming the rhythm of sedimentation in the case considered to coincide with the rhythm of the equinoxes, Dr. Gilbert estimates the time represented by the Benton, Niobrara, and Pierre epochs as 20,000,000 years, or, allowing the number 2 as a factor of safety, between 10,000,000 and 40,000,000 years.

We have received the Supplement to the Calendar of the Royal University of Ireland for 1895, containing examination papers set last year.

So little attention is generally paid in public libraries to the wants of students of science, that we are glad to give a word of praise to a catalogue of books on mathematics, mathematical physics, engineering and architecture, contained in the two public libraries at Halifax. The list has been compiled by the librarian, Mr. J. Whiteley, and it should be found a useful guide to the scientific literature in the two libraries.

The *Bulletin* of the American Museum of Natural History (vol. vi.) has been received. Among the articles in the volume, we notice one "On the Birds of the Island of Trinidad," by F. M. Chapman; "On the Seasonal Change of Colour in the Varying Hare (Lepus Americanus)" by J. A. Allen; "Fossil Mammals of the Lower Miocene White River Beds," by H. F. Osborn and J. L. Wortman. There are also papers on North American Orthoptera and Moths, by W. Beutenmüller; on some North American Mammals, by J. A. Allen, and by F. M. Chapman; and on new forms of marine algæ from the Trenton limestone; by R. P. Whitfield.

The authorities of the Royal Gardens, Kew, publish a "Hand-list of Ferns and Fern-allies cultivated in the Gardens." This remarkably rich collection consists of 802 species and varieties of ferns, and 48 of fern-allies and natives of this country; besides no less than 586 varieties of British ferns. This latter collection is due to the bequest of Mr. W. C. Carbonell, who left it to the Gardens. It consists of 4261 specimens, found by him at Rhiew Castel, Usk, Monmouthshire. The rest of the collection owes its completeness largely to the zeal and assiduity of the late Mr. John Smith, curator of the Gardens from 1841 to 1863.

The text of a series of six Lowell lectures, by Prof. Gantano Lanza, on "Engineering Practice and Education," which has been appearing in the *Journal* of the Franklin Institute since May 1894, is now concluded. Some interesting examples are given of the engineering works of the world, and the functions of the engineer are passed in review. Prof. Lanza holds sound ideas as to the education of an engineer. "There are two things," he says, "which are absolutely necessary to make a successful engineer: first, a knowledge of scientific principles and of the experience of the past; and second, his own experience. . . . The two fundamental sciences upon which the scientific principles of engineering are especially dependent are mathematics and physics, and no proper course in engineering can be arranged without insisting upon these as fundamentals." He shares the general opinion that the education of the engineer should include some knowledge of the differential and integral calculus, if not of higher mathematics.

We have often found occasion to express satisfaction at the work carried on by many local scientific societies. Labourers in the field of science are not wanting, but their work frequently needs direction. Wisely organised, the multitude of willing amateur observers can greatly assist the growth of natural knowledge. A programme just received from the Yorkshire Naturalists' Union, showing the excursions, meetings, and committees of research for 1895, is a sufficient proof that the operations of the Union are conducted with definite objects in view. There is a boulder committee, appointed to collect information as to the distribution of erratic blocks in the county of York; a committee to observe the present changes and past condition of the sea-coast, in order to determine the rate of erosion; a fossil flora committee, which aims particularly at determining the vertical range of the genera and species of the various formations; a geological photographs committee; a

committee to promote the investigation of the marine zoology of the Yorkshire Coast; a micro-zoology and micro-botany committee; a committee to consider proposals for the legislative protection of wild birds' eggs; and a committee having for its object the investigation of the mycological flora of Yorkshire. Upon each of the committees we notice the names of numerous well-known scientific workers; and, as the committees co-operate, when possible, with British Association committees, the Union forms the connecting link between the local societies and the Association. This kind of organisation seems to be the one calculated to produce the greatest amount of useful work. While referring to natural history societies, we may mention that the West Kent Natural History, Microscopical, and Photographic Society has sent us their report for 1894-95. The report contains an address by the President, Mr. H. J. Adams, on "Colour Photography," and a paper on "The Birds of Blackheath," by Mr. H. F. Witherby.

H. MOISSAN has attempted to produce argon compounds by acting on argon, under various conditions, with some of the rarer elements which unite more or less readily with nitrogen (*Comptes rendus*, May 6). 100 c.c. of the new gas were placed at his disposal by Prof. Ramsay. In a part of this, titanium, boron, and lithium were strongly heated without apparent change. Similarly, uranium (containing 3½ per cent. of carbon) did not absorb an appreciable amount of the gas when heated with it for twenty minutes. A quantity of the gas was conducted into a platinum tube of special construction, and there exposed to the action of pure fluorine, both at the ordinary temperature and in presence of induction sparks; in neither case could any reaction be observed whatever the proportion of argon present. The difficulty of manipulating fluorine has not allowed of the effect of long-continued sparking being observed. The results were entirely negative; under the conditions of these experiments, no compounds of argon have been produced.

BY saturating an ethereal solution of ferric chloride with nitric oxide, and concentrating the product at the ordinary temperature in the vacuum desiccator, V. Thomas has succeeded in obtaining crystals of the composition $FeCl_2.NO.2H_2O$. (*Bull. Soc. Chim.* [3], xiii.-xiv. No. 8). The anhydrous compound may be obtained in smaller yellow crystals by crystallisation at 60° on a porcelain plate. Peligot found that nitric oxide dissolved in ferrous chloride solution in the proportion required to form a compound $2FeCl_2.NO$, and this solution lost all its gas on heating. It is interesting and significant that the new crystalline product dissolves completely in cold water without evolution of gas to form a pale yellow solution, and that the solid compound is quite stable in vacuo at the ordinary temperature. Of considerable interest also is the observation by the same author, that nitric oxide gives abundant crystalline precipitates when passed through solutions of antimony tribromide or antimony trichloride.

A NEW series of iron nitrosocompounds have been discovered, by K. A. Hofmann and O. F. Wiede, which possess interest both from the point of view of the gas-analyst and in consequence of the example they afford of the synthetical production of complex inorganic substances. A current of nitric oxide is passed through a concentrated solution of 200 grams ferrous sulphate and 300 grams of potassium thiosulphate. A compound is precipitated in red-brown leaflets, which has the composition $Fe(NO)_2S_2O_3K.H_2O$. This substance may be dried in the vacuum desiccator without change. It is difficultly soluble in water, and dissolves in concentrated sulphuric acid without decomposition, giving an intensely greenish yellow coloured solution. Ammonium and sodium salts of similar composition and properties have also been prepared. The formation of the new acid, dinitrosoferrothiosulphuric acid, of which these salts are derivatives, is facilitated by the presence of an excess of ferrous salt. It may be considered that the essential reaction in its formation consists of a replacement of the group (KS_2O_3) by NO in ferrous potassium thiosulphate, viewing the latter as $KO_3S_2.Fe.S_2O_3K$. The displaced radical probably forms potassium tetrathionate which does not react further. Cobalt compounds, in which the cobalt replaces the iron in this series, can be obtained, though with much greater difficulty. The connection of these new substances with the tetra- and hepta-nitroso compounds of Pawel and Marchlewski and Sachs is yet under investigation.

THE additions to the Zoological Society's Gardens during the past week include two Arabian Baboons (*Cynocephalus hamadryas*, ♂ ♀) from Somaliland, presented respectively by Mr. Francis G. Gunnis and Mrs. E. Lort Phillips; a Japanese Ape (*Macacus speciosus*, ♂) from Japan, presented by Dr. G. L. Johnston; a Rhesus Monkey (*Macacus rhesus*, ♂) from India, presented by Messrs. A. S. and E. Boatfield; a Naked-footed Owlet (*Athene noctua*), European, presented by Mr. Walter Chamberlain; a Black Tanager (*Tachyphonus melaleucus*) from Brazil, presented by Mr. Edward Hawkins; a Hawfinch (*Coccothraustes vulgaris*), British, presented by Mr. H. G. Devas; two Common Peafowl (*Pavo cristatus*, ♂ ♀) from India, presented by Mr. L. G. Whatman; two Pyrenean Newts (*Molge aspera*) from Lac d. Oncet, Pyrenes, presented by Dr. Jacques de Bedriaga; two Indian Pythons (*Python molurus*) from India, presented by Mr. G. Stephen; a Koodoo (*Strepsiceros kudu*, ♀) from Somaliland, a Kinkajou (*Cercoleptes caudivolvulus*, ♀), a Ring-tailed-Coati (*Nasua rufa*) from Brazil, a Dusky Bulbul (*Pycnonotus obscurus*) from Morocco, deposited; two Ruddy Sheldrakes (*Tadorna casarca*, ♂ ♀), European, a Red-fronted Amazon (*Chrysotis vittata*) from Porto Rico, a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Guiana, purchased; a Large Red Flying Squirrel (*Pteromys inornatus*) from India, received in exchange; two Japanese Deer (*Cervus sika*, ♂ ♀), a Barbary Sheep (*Ovis tragelaphus*, ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ALGOL.—The periodic variations in the intervals between the minima of Algol have been explained by Dr. Chandler by supposing that the bright star, with its eclipsing companion, revolves round a distant centre of gravity determined by its relation to another dark body. M. Tisserand, however, considers that the phenomena may be produced by the changes in the line of apsides due to a polar compression of Algol (NATURE, vol. li. p. 328). The latter hypothesis requires that considerable variations in the duration of the minima should be observed; while, on Dr. Chandler's hypothesis, there should be a periodic inequality of the proper motion of Algol. Prof. Lewis Boss has recently discussed the question from the point of view of the proper motion of the star; but since the coefficient is probably less than 0″·7, the investigation is a very delicate one. Taking the result of his computation, apart from any considerations of the behaviour of Algol as a variable star, Prof. Boss is of opinion that there is a preponderance of probability in favour of the real existence of a periodic element in the proper motion, such as is required by Dr. Chandler's hypothesis. Supposing them to be real, they indicate that the apparent motion is in an ellipse, the semi-axis major of which is 0″·522 ± 0″·103 and the semi-axis minor 0″·224; the position angle of the northern end of the major axis is 34, and the inclination of the real orbit to our line of sight is 23°. The computation further indicates that the star passed the major axis of the apparent orbit within three or four years of the most probable date derived from the observated light-changes. Prof. Boss considers the evidence in favour of Dr. Chandler's hypothesis to be sufficient to justify a very thorough investigation of the meridian observations, as well as continued determinations of position. (*Astronomical Journal*, No. 343.)

PARALLAX AND ORBIT OF η CASSIOPEIÆ.—Twenty-seven photographs of the region round this star, taken by Dr. Rutherford

more than twenty years ago, have been utilised by Mr. H. S. Davis for the determination of the parallax (*Astronomical Journal*, No. 343). Six pairs of comparison stars were employed, and the combined results give the value $0''.465 \pm 0''.044$, corresponding approximately to a distance of η Cassiopeiæ from the earth of 43,113,000,000,000 miles, or $7\frac{1}{3}$ light years. Though the new value exceeds previous ones, it is not considered improbably large if the Rutherford plates are subject to no systematic error. Using Grüber's values of the orbital elements, the combined masses of the components is two-tenths as great as that of the sun, and the distance between the components 19 astronomical units, the relative orbit thus being about the same size as that of Uranus. These numbers, however, may require some modification, as Dr. See has recomputed the elements of the orbit, with the results slightly differing from those adopted by Mr. Davis. Dr. See states that during the next ten years the position angle will increase from 204° to 251°, while the distance will diminish from $4''.52$ to $3''.33$.

A Belgian Astronomical Society.—A Société Belge d'Astronomy has been founded at Brussels. The object of the Society is to popularise astronomy and the sciences connected with it (geodesy, meteorology, terrestrial physics, &c.), and to encourage research into the domains of those branches of knowledge. The President of the Society is M. F. Jacobs, and among the Council are General Tilly, Prof. Dusausoy, Prof. Goemans, M. Lagrange, Prof. Pasquier, Prof. Rousseau, and M. Terby. Two of the Secretaries are M. Stroobaut and M. Vincent, both observers at the Royal Observatory, Brussels.

THE IRON AND STEEL INSTITUTE.

THE annual spring meeting of the Iron and Steel Institute was held on Thursday and Friday of last week, in the theatre of the Society of Arts, under the chairmanship of the new President, Mr. David Dale. The following is the list of the papers set down for reading :—

"On Metal Mixers, as used at the Works of the North-Eastern Steel Company," by Mr. Arthur Cooper.

"On the Effect of Arsenic upon Steel," by Mr. J. E. Stead.

"On the Iron Ore Mines of Elba," by Mr. H. Scott.

"On the Manufacture of Steel Projectiles in Russia," by Sergius Kern.

"On Ternary Alloys of Iron with Chromium, Molybdenum, and Tungsten," by James S. De Benneville, of Philadelphia.

The last two papers were taken as read. After the usual formal proceedings, the President presented the Bessemer medal, which had this year been awarded to Mr. H. M. Howe, of Boston, U.S.A. As Mr. Howe was not able to be present, Prof. Roberts-Austen accepted the medal on his behalf.

Mr. Dale next proceeded to read his inaugural address. Those who know the good work done by Mr. Dale in the conciliation of labour disputes will not be surprised to learn that the chief interest of the address was in the domain of economics rather than metallurgy. The address was none the less welcome on this account, as no class are more affected by disturbances in the labour market than the iron and steel makers. Mr. Dale showed very clearly the disastrous effects upon British trade of strikes and industrial disputes, and dwelt upon the ever-enlarging area of competition in the manufacturing markets of the world; for now we have not only the continental nations of Europe to contend with, but have to meet the products of the still cheaper labour of the far East.

Mr. Cooper's paper, though short, supplied a valuable contribution of knowledge to the practical steel maker. Uniformity of product is at once one of the most desirable and most difficult things for the steel maker to secure. No matter what care may be taken, the product of the blast furnace will vary in regard to those minute percentages of alloys which exercise so important an influence on the characteristics of the steel producer. Efforts have been made to equalise the analysis of the pig iron by mixing the ore, but these have been only partially successful. It is desirable, from an economic point of view, that molten iron should be taken direct from the blast furnace and used in the converter; but, in the basic process, the need of uniformity has prevented this course being followed. It has been therefore necessary to follow the original plan of running the molten iron from the blast furnace into pigs, and then remelting it in cupolas. In this way, by using the product of several furnaces, and by a system of careful analysing and selection, uniformity has been generally obtained. In spite of all care taken, however, there will be at times differences in the product of the cupolas, owing to irregularities in working which could not be guarded against, and it would frequently happen that though a standard mixture of pig might be charged into the cupola, the amount of silicon or manganese would vary considerably, owing to larger quantities of these metals being oxidised at one time than another. The mixer is a vessel in appearance like a large Bessemer converter. Into this the molten metal from the blast furnace is run, together with a certain amount of cupola iron in the case of the North Eastern Steel Company's works, with the plant of which the paper deals. The mixer is largely used in America, Mr. Carnegie stating during the discussion that at his works they were about to erect some of 600 tons capacity. The mixers, of which there are two at the North Eastern works, are each 150 tons capacity. For drawing the metal off into the ladle the mixer is tilted, swinging on trunnions like a converter, hydraulic machinery being provided for the purpose. In the discussion which followed the reading of the paper, many steel makers corroborated the account, given by the author, of the excellent results obtained by the use of the mixer.

The chief feature of the meeting was the reading and discussion of Mr. Stead's excellent contribution on the effect of arsenic in steel—a paper we should have described as exhaustive had it not been that the author states he is about to follow up the experiments of which he gives an account by further investigation in the same field. Mr. Stead commenced by a reference to the well-known memoir on the same subject, which Messrs. Harbord and Tucker contributed to the meeting of the Institute held in 1888. In that paper it was shown that a large quantity of arsenic is decidedly injurious to steel; and it has generally been thought that smaller quantities would be similarly injurious in a corresponding degree. Mr. Stead did not consider such an hypothesis necessarily sound, and determined to carry out the elaborate series of experiments, details of which are given in the paper. The results, as we have said, are of the utmost importance to steel makers, for arsenic and phosphorus are frequently bracketed in analyses, as the separation of the two is a long and tedious process. If small quantities of arsenic are not injurious, as would appear from Mr. Stead's investigations, phosphorus is undeniably a deleterious ingredient.

The general conclusions the author drew from his investigations were that between 0·10 per cent. and 0·15 per cent. of arsenic in steel for structural purposes does not have any material effect so far as mechanical properties are concerned. The tenacity is but slightly increased, the elongation is apparently not affected, and the reduction in area of the fractured test-pieces is practically equal to that of the same steel without the addition of arsenic. With 0·20 per cent. arsenic the difference, although slight, is noticeable in samples of acid open-hearth steel tried; but even in this case the only serious difference evidently caused by the arsenic is the inferiority of the bending properties of the pieces cut from the plates across the direction of rolling after they had been tempered. With larger amounts of arsenic the effect is decisive. When 1 per cent. is present the tenacity is increased, and the elongation slightly reduced. The bending properties of the steel are, however, fairly good. When the arsenic amounts to about $1\frac{1}{2}$ per cent. the tenacity is still further increased, and the elongation and contraction of area still further reduced, whilst the bending properties are poor. With 4 per cent. of arsenic the tenacity is increased, and the contraction becomes *nil*. The author points out, however, that the trials with steel containing the higher percentages of arsenic could not be considered quite satisfactory, because the ingots on which the experiments were made were of very small size, and consequently a small amount of work only could be put upon them before testing. Mr. Stead considered it would have been highly probable that had larger masses been dealt with the results would have been more satisfactory. The effect of quenching the steel, after heating to a red heat, in every case where arsenic was in large quantity, was to improve its bending property.

Hot working is not affected by even 4 per cent. of arsenic, such an alloy appearing to stand about as much heat without burning as a steel containing 1 per cent. of carbon. When heated below the burning point such material can readily be hammered and rolled, and appears to be as soft in that state as steel containing about ·05 per cent. carbon. From this the author considers it safe to conclude that arsenic has not the slightest tendency to produce red-shortness. Mr. Stead had

made experiments to ascertain the rate of corrosion of arsenical steel. He had submerged wires in a 2 per cent. solution of sal-ammoniac, had placed others in fresh water, and still another sample to a pile of the wharf at the Middlesbrough Ironworks in such a position as to be alternately covered and exposed as the tide ebbed and flowed. The conclusions arrived at were that arsenical steel is not more liable to corrosion than the same material without arsenical addition; in fact, oxidation is retarded by the presence of small quantities of arsenic.

It is in steel that is to be used in positions where it will require to be welded that arsenic appears most injurious, for that process is rendered more difficult by even very small quantities of arsenic; so that, as Mr. Stead says, when welding material is required, arsenic should be most carefully avoided. In regard to electrical conductivity, too, arsenic is injurious, for the value of the material in this respect is materially reduced by even small quantities of arsenic. A quantity equal to 0·25 per cent. diminishes the conductivity by about 15 per cent.

The paper concludes with an appendix in which the author gives a method he has worked out in detail for determining the arsenic in iron ores, in steel, and in pig iron. It has been the general practice to precipitate the arsenic as sulphide or hydric sulphide from the distillate, and either weigh the pure sulphide after drying at 212° F. or to oxidise it in bromine and hydrochloric acid, and then precipitate the arsenic acid with ammonia and magnesia solution, and weigh the precipitate produced. This process, although accurate, is tedious and takes at least twenty-four hours to complete. Mr. Stead has found that if the distillation is conducted in a special manner the whole of the arsenic may be obtained in the distillate, unaccompanied with any traces of chloride of iron, and that if the hydrochloric acid is nearly neutralised with ammonia and finally completely neutralised with acid carbonate of soda, the arsenic can be determined volumetrically with a standard solution of iodine, using starch solution as an indicator.

Émil Fischer proposed the process of distillation with ferrous chloride and titration of the distillate with iodine solution; but, as the details are not given in "Crookes' Select Methods," Mr. Stead had to work them out for himself. These he gives in full in his paper, to which we must refer our readers, as it would take too much space to describe the process in full. Mr. Stead says that a more simple and accurate device for the determination of small quantities of arsenic it would, he thinks, be impossible to conceive.

The discussion of this paper, although of an interesting nature, did not produce any new facts of importance. The majority of those who spoke were either steel makers or those interested in the production of steel, and they naturally congratulated themselves on the conversion of a long-supposed enemy into a neutral, if not into an ally. It should be remembered, however, that the meeting consisted chiefly of persons only too anxious to reduce the difficulty and cost of steel making; and not likely to accept any explanations tending to that end in a captious spirit. No one is likely to question the scientific accuracy or *bona fides* of so eminent and conscientious an observer and experimentalist as Mr. Stead, yet there may be something to say on the other side. This appears more likely from the remarks of the one user of steel who spoke—Mr. Wigham, the manager of a wire-drawing firm—who had made a report to Mr. Stead, which was quoted in the paper. It should be remembered, also, that Mr Stead himself says that further experiments are necessary.

The only remaining paper that was read was Mr. Scott's contribution on the Iron Mines of Elba. This was not discussed.

The autumn meeting of the Institute will take place in Birmingham, commencing Tuesday, August 12.

THE SCHORLEMMER MEMORIAL LABORATORY.

An interesting ceremony took place at the Owens College, Manchester, a few days ago, when Dr. Ludwig Mond formally opened the Schorlemmer Laboratory for Organic Chemistry, together with a large laboratory for medical students and a room for the preparation and storage of reagents. It may be remembered that, after the death of Prof. Schorlemmer, his friends and pupils, under the lead of Sir H. E. Roscoe, late professor of chemistry at the College, took steps with a view to fittingly commemorate his services to the College and to the advancement of organic chemistry. It was generally felt that the best memorial would be the erection of a laboratory for organic chemistry, to be called after his name, and a subscription list was accordingly opened. The appeal, which was generously headed by Dr. Mond, was so well responded to, both in this country and in Germany, that in a short time a sum of £2500 was subscribed. Meantime the Council of the College had to take into serious consideration the rapid growth of the chemical department. Originally designed for 100 students, the laboratories had for several years been overcrowded, and the private rooms built for research work had to be given up for the general instruction of the students. The number of the students in the chemical laboratories has steadily increased during the past five years, and, in view of this increase, the Council became convinced of the necessity of extending the chemical department. They accordingly accepted the fund raised by the Schorlemmer Memorial Committee, and instructed Mr. Alfred Waterhouse to prepare plans for a "Schorlemmer" Organic Laboratory, and for a new laboratory for elementary students, on a plot of land adjoining the present laboratories acquired by the College for the purpose of their extension. The Schorlemmer Laboratory, designed by Mr. Waterhouse, is at the end of the main corridor in the old chemical building. It measures sixty feet by thirty feet, and has an arched roof thirty feet high. The laboratory is designed to accommodate a professor, two demonstrators, and thirty-six students. It is fitted in the most complete manner with every requisite for the important work which is to be carried on within it, and in some particulars is arranged after the plan of the Munich organic laboratories. The lower laboratory is designed for forty-five students. The fittings are similar to those in the old laboratories designed by Sir Henry Roscoe. The total cost of the new building was £4800.

A full report of the opening ceremony is given in the *Manchester Guardian*, to which source we are indebted for the following condensed account:—

In connection with the inaugural proceedings, a large and representative company gathered in the Chemical Theatre of the College. Messages regretting inability to attend, and wishing prosperity to the laboratory, were received from a number of eminent chemists. Prof. H. B. Dixon referred to the esteem in which Schorlemmer's name was held, and expressed, on behalf of his colleagues and himself, their admiration of the life and character of the man to whose memory the laboratory had been erected.

Sir H. E. Roscoe sketched Schorlemmer's life, and, in the course of his address, said:—Schorlemmer added another name to the list of distinguished foreigners who had found a home in these islands. Never again could it be said that England failed to recognise and appreciate the value of the services of those who sought her shores. The names of Herschel, of Hofmann, of Max Müller, and, lastly, of Schorlemmer indicated that we are not slow to give honour to those who were once strangers in the land, but who had made themselves members of our national family. They might have good hopes that the time would soon come when the leaders in chemical industry would appreciate the necessity of a thorough scientific training, as had long been the case in Germany; and that as Giessen was, under Liebig, the means of raising the standard of chemical education throughout the Fatherland, so the chemical department of Owens College might, under the direction of Prof. Dixon and Prof. Perkin, the director of the new laboratory, be pointed out as the institution in England which had done the same for this great empire.

Dr. Ludwig Mond next addressed the meeting. He remarked that the opening of the first laboratory solely devoted to the study of organic chemistry, at the only University in England which could boast of a professor of that science, was a distinct step forward in the development of science in this country. He considered it a great step in advance to have a special laboratory and special professors appointed for the study of the chemistry of carbon, because the subject-matter of chemistry now covered so vast a domain, and was increasing at such an immense rate, that for any one desiring to further contribute to it, it had become a necessity, after mastering the main facts of the science, to give his attention specially to the details of one or other part of it. While it was true that carbon was only one out of many elements, it possessed such very special properties that the multitude of its compounds probably outnumbered those of all the rest of the elements together, and it had the unique interest that all the innumerable substances that were found in plants and animals, which built up their tissues, and by their constant changes produced the phenomenon we called life, were all

compounds of carbon. It was for this reason that they called the chemistry of these compounds organic chemistry, and it was very natural that that branch of their science should be nearer to their hearts than any other branch. But there was another and stronger reason for having special laboratories of organic chemistry. The methods of investigation and the way of analysing organic compounds differed considerably from those applied to inorganic chemistry. In the latter, if we had ascertained by an accurate analysis of a pure substance its percentage composition, that, together with the determination of a few simple physical properties, was usually sufficient to give us a perfect insight into its chemical composition and behaviour. The laboratory methods required for that study were simple and most of them well known, so that they could be acquired by sufficient experience. In organic compounds the matter was very different. The percentage composition and the physical properties told them very little of their chemical individuality and behaviour. Many substances of exactly the same percentage composition possessed widely different qualities, which were not explained by their physical properties. They must find out how these compounds, many of which were very complex, were built up. They had to unravel the structure of those substances to attain their end, which in chemical investigation always meant to give an explanation of all the various properties of a substance through its chemical constitution. To ascertain its structure they had to break the organic substance down by degrees, to take it gradually to pieces; and even that was not enough, but to make sure of the actual arrangement of those pieces in the substance they had to put them together again, to rebuild the substance from its proximate constituents, and only after having accomplished that could they consider that they knew its constitution. The methods employed in that work were entirely different from those of ordinary analysis. They were very manifold. The investigator had to make his own choice which of them to apply in any individual case, and wherever he broke new ground and undertook the study of a new series of compounds, he had to discover and work out new methods before he could achieve success. It was evident that a student who aimed at qualifying himself for such high-class work should enjoy special facilities, and should, after having gone through a regular course of analytical chemistry, have a chance of prosecuting special organic work in a laboratory fitted specially for it, and where he was undisturbed by the army of beginners who thronged an analytical laboratory. And there he might point out that in his opinion the reason why this country had not advanced in organic chemistry as fast as other countries, the reason why Hofmann's prediction in his report on the Exhibition of 1862 that "England will be unquestionably at no distant date the greatest colour-producing country in the world," had not been fulfilled, and that Germany had almost entirely taken this industry out of her hands, although it was inaugurated by an Englishman (Dr. W. H. Perkin), had been that so few English students of chemistry had devoted sufficient time to the prosecution of their studies. It was evident, therefore, in order to attain the necessary experience and certainty in carrying out original investigation in organic chemistry, that four to five years of close study and attention, under the leadership of a competent professor, were a necessity: and for carrying on successfully the manufacture of artificial colours it was indispensable that the chemist should be able to carry out independent original research because new colours had year after year to be discovered and manufactured, and the processes for their production had to be constantly improved in order to compete successfully with rival manufacturers. The success of an industrial enterprise depended not, indeed, upon the workman, not the foreman, as so many people in this country still believe, but upon the leading mind who directed the manufactory, who had a thorough grasp of scientific principles and had been trained to habits of scientific thought. He agreed that it was desirable to cultivate physical chemistry and inorganic chemistry much more than had been done, and he was very glad that the great supremacy which organic chemistry had enjoyed more particularly in Germany, the home of chemistry was now being contested by other and equally important branches of the science. But great, and very great, as had been the progress of organic chemistry, it had greater and more important problems still to solve; and in this country, which had given birth to so many of the most important steps in advance of that science, it had not received that amount of general attention which it had deserved in the past, and which it still deserved in the future. He therefore specially and heartily welcomed the opening of the first laboratory exclusively devoted to it in England. Prof. Schorlemmer, in his excellent and most suggestive little work "On the Rise and Development of Organic Chemistry," after giving a lucid review of the steps by which the great edifice of that science had been built up, gave in his concluding remarks a perspective of the problems still to be solved wide enough for the most expansive imagination of any searcher after truth. If to-day we still could not make morphine, quinine, and similar bodies artifically, the time was near at hand. If we could not make quinine, we had already found a partial substitute in antipyrine, and its introduction into therapeutics had lowered the price of quinine considerably. Another important problem was the synthesis of the ingredients of our daily food, such as sugar, gum, and starch. Those bodies were nearly related to each other, for we could convert the two latter into different kinds of sugar, and sugars again into gums. That the synthesis of sugar was imminent had already been stated. But it was quite different with those important parts of our food which had been called the albuminous bodies. Kekulé, in discussing the scientific aims and achievements of chemistry, brought forward the idea that if ever chemists should succeed in obtaining albuminoid bodies artificially it would be in the state of living protoplasm, perhaps in the form of those structureless beings which Haeckel called the "Monera." All attempts hitherto made for the purpose of producing living matter artificially had failed. The enigma of life could only be solved by the synthesis of an albuminous compound. Prof. Fischer, in a lecture delivered not long ago in Berlin, also expressed himself full of confidence that the time would arrive when we might attack successfully even the problem of the constitution and synthesis of the albuminoids, and might thus approach the problem of the origin of life. Surely with such a prospect before them as the ultimate result of the pursuit of organic chemistry, no amount of work, no amount of thought, no amount of time and trouble devoted to that study would be too much if it was well employed in leading successfully to the great end in view, although the goal might not be reached for generations to come.

The company afterwards adjourned to the new laboratory, which was declared open by Dr. Mond.

THE MIGRATIONS OF THE LEMMING.

UNDER the title "Myodes Lemmus, its Habits and Migrations in Norway," Prof. R. Collett, of Christiania, gives a valuable account of his researches into the habits and migrations of that interesting little rodent, the lemming, which has become so notorious on account of its periodic wanderings in vast hordes down the Scandinavian valleys. Prof. Collett finds the earliest notice of the lemming in an old Norse manuscript dating from the latter end of the thirteenth century, and reproduces a curious and striking woodcut from the great history of Olaus Magnus (1555), in which is graphically figured the descent of the lemmings from the clouds according to the prevalent belief. But the most valuable parts of the memoir are those which depend upon the author's personal knowledge of the lemming. The nature and habits of the lemming are clearly described, and much light is thrown upon the causes which from time to time lead such vast numbers of these animals to leave their native uplands and to begin their suicidal wanderings. The migrations seem to be directly due to over-population. In certain years, termed by the writer "prolific years," an abnormal fecundity is exhibited by the lemming; this phenomenon is not, however, confined to this species, but is shown also in numerous families of mammals, birds, and insects. The consequences of this great multiplication in the case of the lemming are thus described by Prof. Collett. "The enormous multitudes require increased space, and the individuals, which, under normal conditions, have each an excessively large tract at their disposal, cannot, on account of their disposition, bear the unaccustomed proximity of the numerous neighbours. Involuntarily the individuals are pressed out to the sides until the edge of the mountain is reached. In a short time they enjoy themselves there, and the old individuals willingly breed in the upper regions of the forests, where, at other times, they are entirely wanting. New swarms, however, follow on; they could not return, but the journey proceeds onwards down the sides of the mountains, and when they once reach the valleys, they meet with localities which are quite foreign to them. They then continue blindly on, endeavouring to find a home corresponding to

that they have left, but which they never regain. The migratory individuals proceed hopelessly on to a certain death." Sooner or later all the wanderers meet their death—thousands are drowned in rivers or fjords, thousands are attacked by beasts and birds of prey, and thousands perish from the effects of cold and damp; but the greater number die from the effects of a peculiar epidemic which attacks them in the lowlands. It is pointed out by the writer that the wandering instinct developed during migratory years is probably of distinct service to the species in reducing the surplus population.

THE AUSTRALASIAN ASSOCIATION.

WE gave, a fortnight ago, the presidential address delivered by the Hon. A. C. Gregory to the Australasian Association for the Advancement of Science at this year's meeting in Brisbane. Full reports of the proceedings in the different Sections have reached us, from the General Secretary, Mr. J. Shirley, but limits of space prevents us from printing more than a brief summary of them.

The public proceedings of the meeting were opened by a popular lecture on "Star Depths," by Mr. H. C. Russell. Mr. Russell traced the growth of knowledge concerning the distance of the stars, and the structure of the stellar universe, and illustrated his description by a selection from the excellent photographs of celestial scenery taken at Sydney Observatory.

We give a synopsis of the work of the various sections.

ASTRONOMY, MATHEMATICS, AND PHYSICS.

Mr. Alexander M'Aulay, as President of Section A, delivered an address "On Some Popular Misconceptions on the Nature of Mathematical Thought."

Mr. P. Baracchi, contributed a paper on "the most probable value and error of Australian longitudes, including that of the boundary lines of South Australia with Victoria and New South Wales." Dr. Ralph Copeland sent "Some Notes on the New Royal Observatory, Edinburgh," and Mr. H. C. Russell read a paper "On a Photographic Transit Instrument."

CHEMISTRY.

Mr. J. H. Maiden delivered the presidential address in this Section, entitled, "The Chemistry of the Australian Indigenous Vegetation." Mr. E. A. Weinberg contributed a paper on the refractory gold ores of Queensland: their sources and treatment. Prof. A. Liversidge, F.R.S., read a paper on "Variations in amount of Ammonia in Water on keeping." He also described the internal structure of some Australian nuggets, of different sizes, which had been closely examined and photographed. The etching was conducted according to the following plan:—A clean section was made and highly polished, and acted upon by chlorine water or bromine water, tincture of iodine or potassium cyanide, or sodium chloride mixed with nitric acid. The crystals less readily soluble stand up in relief and resemble the well-known figures seen in metallic meteorites when etched. One curious fact observed was that when the nuggets were subjected to heat, bubbles or blebs were formed on the surface, which burst with a sharp report, probably due to water included in the nugget being converted into high-pressure steam. Several beautiful photographs showing the crystalline nature of the nuggets were exhibited. Other papers read were: "On the Corrosion of Aluminium," and "Contributions to the Bibliography of Gold," by Prof. Liversidge; "Pharmacy as a Science and its Future," by Dr. W. Finselbach; "Notes and Analyses of some of the Artesian Waters of New South Wales," by John C. H. Mingaye; "On the Economic Treatment of Gold Ores," by Geo. H. Irvine; "Queensland Native Astringent Medicines," by Dr. Joseph Lauterer; "Portland Cement after Fifty Years," by W. M. Doherty; "Some Remarks on the Teaching of Elementary Chemistry," by A. J. Sach; "Analysis of Eucalyptus Gums," by Dr. Wilton Love; "The Ointments of the British Pharmacopœia," by F. W. Simmonds; "Notes on the Poisonous Constituents of Stephania Hernandiiafolia," by Prof. Edward H. Rennie; "Preliminary Notes on the Bark of Carissa Ovata, *R. Br.* v. Stolonifera, *Bail*," by H. G. Smith; "On a Method of Shortening certain Chemical Calculations," by W. A. Hargreaves.

GEOLOGY AND MINERALOGY.

Prof. T. W. Edgeworth David, in his address to this Section, reviewed briefly some recent geological discoveries of special interest. A paper by Mr. E. F. Pittman, Assoc. R.S.M., entitled "Notes on the Cretaceous Rocks in the North-western Portion of New South Wales," gave the results of a recent geological journey by him over 1150 miles of country. The geological examination was made chiefly with the object of determining approximately the area and boundaries of the artesian water formation.

Among other papers read before this Section were:—"Anticlines and Synclines and their Relation to Mining," by Ernest Lidgey; "On the Nomenclature of Crystals," by Prof. A. Liversidge, F.R.S.; "The Development and Progress of Mining and Geology in Queensland," by William Fryar; "On the Present State of our Knowledge of the Older Tertiaries of Southern Australia," by G. B. Pritchard; "The Antiquity of Man in Victoria," by W. H. Ferguson; "The Glacial Deposits of Victoria," by G. Officer, L. Balfour, and E. G. Hogg; "Notes on Tin Mining at Herberton," by John Munday.

BIOLOGY.

Prof. A. Dendy took for the subject of his presidential address, "The Cryptozoic Fauna of Australasia." Mr. F. M. Bailey read a paper on peculiarities of the Phanerogamic Flora of Queensland. The paper chiefly contained descriptions of indigenous fruits recommended for cultivation. Mr. D. Le Souef furnished a paper on the Tree Kangaroo (*Dendrolagus Bennettianus*), describing its mode of climbing, its food, and the way it is captured by the natives. In a paper on the eating of earth by the larger Macropodidæ, by J. Douglas Ogilby, evidence was given of the eating of earth by kangaroos in the Bourke district, New South Wales. This habit does not appear to have been previously recorded, though in the district under notice it plays no unimportant part in the economy of the larger marsupials.

Dr. M. C. Cook sent a paper entitled "Pestiferous Fungi and their Modes of Attack." Dr. Charles Chilton gave a general account of history, occurrence, distribution and habits of the blind Amphipoda and Isopoda found in the underground waters of the Canterbury Plains in New Zealand. Miss Lodder furnished a revised list of the Marine Mollusca of Tasmania. Some plants peculiar to the Burnett Basin were described by James Keys. In a paper entitled "Notes and Observations on the Genus Nephila," W. J. Rainbow dealt with—(1) the localities in which spiders of the genus Nephila abound; (2) the strength and elasticity of their webs, in the sticky meshes of which certain birds of weak wing-power are caught; (3) the question as to whether the Nephilæ eat birds thus captured; (4) the mode by which silk may be obtained from these spiders by artifical means, and the experiments made by certain naturalists with a view to ascertaining the amount that could be obtained from individuals of this genus in a season, the object of which was to endeavour to prove that the product might be used for economic purposes.

Dr. J. Müller, of Geneva, Switzerland, contributed a paper on the Pyrenocarpeæ of the Lichen family. Mr. A. J. Campbell described the nests and eggs of Australian Hawks. Mr. A. G. Hamilton, in a paper entitled "The Fertilisation of some Australian Plants," gave many of his own observations as to the mode by which fertilisation is effected. Mr. W. M. Maskell gave a synoptical list of the Coccidæ reported from Australasia and the Pacific Islands up to December 1894.

Mrs. W. Martin gave the life-history of the vegetable growth known as Native Bread (*Mylitta Australis*). Australian mosses were enumerated by Richard A. Bastow, and some notes on the poisonous constituents of *Stephania hernandiæfolia* were read by E. H. Rennie and E. F. Turner. Picrotoxine and an alkaloid possessing strongly poisonous properties and marked chemical characteristics have been isolated from an extract from the plant.

"Economic Entomology" was the title of a paper by the Rev. E. H. Thompson, who pointed out the great benefit resulting to a country from a properly conducted Government Entomological Department, and urged, in order to increase its usefulness: (1) the formation of a federal entomological department with a head staff and field observers in each of the colonies; (2) a federal agricultural and scientific journal for all the colonies, subsidised by all; (3) elementary entomology to be taught in the State schools, special reference being given to the insect pests peculiar to each district or colony; and (4) the

formation of school museums and prizes given for the best collections.

Mr. G. E. Barton gave a concise historical account of the first discovery of the Eucalyptus, including the names and nationalities of those to whom the honour has been ascribed by various writers.

A paper by Dr. J. Lauterer contained physiological and microchemical researches on the Eucalyptus, and contributed some new items with regard to the life-history of those trees connected with the origin of the gum exuded by their bark.

Geography.

The President of the Section, Baron von Mueller, was absent, but his address, on "The Commerce of Australia with Neighbouring Countries in Relation to Geography," was read.

Mr. C. L. Wragge gave an account of his investigations of ocean currents by means of bottles thrown into the sea. He was of opinion from the results obtained that many of the bottles had been influenced more by winds than by ocean currents; but if this were not the case, the bottles cast adrift in the Australian Bight distinctly indicated that a strong current sets from the neighbourhood of Kangaroo Island towards the head of the Bight and Israelite Bay. The most interesting of the bottle papers is one that was cast adrift near the Cocos Islands, in the north-eastern portion of the Indian Ocean, and which was found a few months afterwards on the shores of German East Africa. Papers cast adrift by Mr. Wragge during a voyage to England, in the neighbourhood of the Sargasso Sea, were picked up at Hayti, on the Alabama coast, and on the Louisiana coast. Others thrown overboard with a view to testing Rennel's current, which sets towards the coast of Ireland, from the neighbourhood of Cape Finisterre, were certainly influenced by the strong west-south-west winds which were experienced on that occasion between the Western Islands and the English Channel. None of these appear to have followed the current, but went straight across it, some being found on the west coast of France, and near the islands of Sein, while one was picked up at Brighton. It appears to be highly desirable, judging from the results obtained, that the bottles should be weighted with sand or other material, with a view to more completely sinking them in the water, and thus minimising the influence of the winds.

Among other papers contributed to this Section were:—"The Southern Alps of New Zealand," by Mr. A. P. Harper; "The Bissagos Islands," by M. Max Astrie; and "Physiography of the Victorian Gold Fields," by James Stirling.

Ethnology and Anthropology.

Mr. Thomas Worsnop, President of the Section of Ethnology and Anthropology, delivered an address upon the prehistoric arts of the Australian Aborigines. Messrs. W. J. Enright and R. H. Matthews described the aboriginal drawings in the Wollombi Caves, New South Wales. A paper was contributed by Mr. Thomas Petrie, on the habits and customs of the wild tribes as he saw them in 1837, from Brisbane to Maroochy. "Foods of North-west Aboriginals" was the title of a paper by J. Coghlan. Mr. John F. Small contributed a paper on customs and traditions of the Clarence River aboriginals. The paper dealt with the traditions, funeral ceremonies, marriage laws, and the Bora ceremony. Mr. J. Thorne read a paper entitled "Curious Aboriginal Marriage Custom." The paper was the result of investigations made by the author in the Laguna Bay.

The other papers communicated to this Section included: "'Boomerang' and 'Woomera,' Evolution, Varieties, and Distribution," by Mr. A. Weston; "The Ancient Government of Samoa," by Rev. S. Ella; "Notes on Tokelau, Gillbert, and Ellice Islands," by Rev. J. E. Newell; "A Comparative View of some Samoan Customs," by Rev. J. B. Stairs; "Early Samoan Voyages and Settlements," by Rev. J. B. Stairs; and "Gaelic Contributions to Folk Lore," by Rev. A. C. Sutherland.

Agriculture.

In a paper on the teaching of agricultural botany, Mr. C. T. Musson said that the object to be aimed at by instructors in agricultural botany should be to impart such information to the prospective cultivator as would make him acquainted with plant structure and the more important useful plants. Practice alone would not make a good farmer, but practice, when based upon a knowledge of the animate and inanimate objects he was dealing with, and their surroundings, would make the man of resources best fitted for his work. Mr. T. B. Guthrie contributed a paper on examinations of different varieties of wheat grown in New South Wales. He also read a paper on "soil analysis," in which the value of soil analysis to the farmer was discussed, and different methods for the determination of the available plant food in soils were reviewed. The paper embodied a suggestion for a scheme of soil analysis, the results of which should be of practical use to the farmer, based upon the determination of those conditions which conduce to fertility rather than to the chemical constitution of the soil. Of the remaining papers read before this section, the following were of more than technical interest:—

"Climatic Influences on Contagious Diseases of Live Stock," by P. R. Gordon; "How to Grow Fruit," by Albert H. Benson; "Floods and Forests," by Philip MacMahon; "Semi-Tropical Horticulture," by Leslie G. Corrie; "Forage Plants and Grasses of Australia," by Fred. Turner; "The Agricultural Chemistry of the Sugar Cane," by Joseph Fletcher.

Engineering and Architecture.

Mr. James Fincham, President of this Section, delivered his presidential address on "Architecture and Engineering."

Prof. W. C. Kernot contributed a paper on wind pressure. The paper was a continuation of one read at the Adelaide meeting. It dealt with the relation between velocity and pressure, and detailed series of experiments leading to the formula $P = \cdot 0033V^2$, which approximates very closely to the rule given by Dines, and disagrees with the rules given by Smeaton and Crosby. The pressure of wind upon roofs was also dealt with, and experiments were quoted to show that the ordinary method of computing the pressure is fairly accurate when the roof is supported on thin columns, so that the wind can pass freely below, but is altogether wrong when the roof is supported on walls. In this latter case the pressure is greatly reduced, and when the walls terminate in parapets is often rendered negative, the roof having a distinct tendency to lift.

Other papers communicated to this section were:—"Experiments on the Waterproofing of Bricks and Sandstones with Oils," and "Experiments on the Porosity of Plasters and Cements," by Prof. A. Liversidge, M.A., F.R.S.; "On Teredo-Resisting River Structures," by Thomas Parker; "Earthquakes in Relation to Building Construction," by Thos. Turnbull.

Sanitary Science and Hygiene.

The President of the Section of Sanitary Science and Hygiene, Dr. J. W. Springthorpe, read an address on "The Teaching of Science in Matters of Health."

Among the papers read were:—"The Promise of 'Serum Therapeutics' in regard to Tuberculosis," by Dr. J. Sidney Hunt; "Contagiousness of Tuberculosis," by F. H. Vivian Voss; "The Prevalence and Intercommunicability of Human and Animal Tuberculosis," by S. S. Cameron; "Leprosy," by Dr. C. E. Dumbleton, and also by A. Francis; and "Etiological Views of the Maintenance of Leprosy," by Dr. J. A. Thompson.

Mental Science and Education.

Prof. F. Anderson, the President of this Section, delivered his address on "Education in Politics."

Dr. Henry Belcher contributed a paper on the use and abuse of examinations. The advantages of the examination system were shortly stated as follows:—It enables the teacher to stimulate the intelligence and test the progress of the pupil, and to fill up flaws and gaps due to imperfect apprehension, carelessness, or defective memory; it is a power almost indispensable to the teacher's efficiency, and is thus a potent factor in general education; it had an alterative and prophylactic effect upon private adventure schools, raising their tone both intellectually and morally. The author doubted whether it was wise to entrust the examination of pupils to persons other than their teachers. The disadvantages of the examination system were that the best part of a teacher's work escapes analysis; methods of higher teaching rise in quality and character, while methods of examination lie behind; by the selection of set books, and the publication of manuals thereon, an intolerable yoke and shackle is placed upon elementary scholarship; examinations appeal to the lower side of human nature—what will pay becomes the pupil's ruling thought. Certain subjects of great importance are neglected because they do not largely count for prizes and honours; and research is altogether neglected.

Among the remaining papers read were:—"Science as a Subject in Girls' Schools," by Miss F. E. Hunt; "The Curriculum of Secondary Education," by D. H. Hollidge; "The Technical Element in a State System of Education," by Antony St. Ledger; "A Contribution towards the Study of the Relation of Ethics and Science," by the Rev. J. S. Pollock; "The Importance of Mental Science as a Guide in Primary Education," by James Rule.

The business of the Association concluded with a meeting of the General Council, at which the following recommendations, among others, were adopted:—

(1) That the committee for the investigation of the thermodynamics of the voltaic cell be reappointed without grant.

(2) That the report of the Seismological Committee be printed, and that the committee be reappointed and allowed a grant of £10 towards the cost of the erection of the instruments presented by Dr. Von Rebeur-Paschwitz at Timaru.

(3) That the following be a committee—namely, Messrs. F. M. Bailey, R. L. Jack, A. Gibb Maitland, A. Meston, C. W. De Vis, and H. Tryon—to investigate the geology, land flora, and natural resources generally of the islands and islets of the Great Barrier Reef.

(4) That the New Zealand Government be asked to set apart Stephen's Island, Cook Strait, as a reserve for the Tuatara Lizard.

(5) That the committee for the investigation of glacial deposits in Australasia be Messrs. Hutton, R. L. Jack, R. Tate, R. M. Johnston, F. W. E. David (secretary), G. Sweet, J. Shirley, W. Houchins, E. G. Hogg, E. J. Dunn, A. Montgomery, and E. F. Pittman.

(6) That a committee—consisting of Messrs. H. C. Stanley, A. B. Brady, Thomas Parker, Prof. Warren, Prof. Kernot, Henry Moncrieff, and James Fincham—be appointed to inquire into the habits of the teredo, and the best means of preserving timber or structures subject to the action of tidal waters.

(7) That the committee on psycho-physical research be appointed without a grant.

The next meeting of the Association will be held at Sydney in 1897, under the presidency of Prof. Liversidge, and the following meeting will take place at Melbourne.

---

*ELECTRIFICATION OF AIR, AND THERMAL CONDUCTIVITY OF ROCK AT DIFFERENT TEMPERATURES.**

(I.) "ON THE ELECTRIFICATION OF AIR.

§ 1. CONTINUOUS observation of natural atmospheric electricity has given ample proof that cloudless air at moderate heights above the earth's surface, in all weathers, is electrified with very far from homogeneous distribution of electric density. Observing, at many times from May till September, 1859, with my portable electrometer on a flat open sea-beach of Brodick Bay in the Island of Arran, in ordinary fair weather at all hours of the day, I found the difference of potentials, between the earth and an insulated burning match at a height of 9 feet above it (2 feet from the uninsulated metal case of the instrument, held over the head of the observer), to vary from 200 to 400 Daniell's elements, or as we may now say volts, and often during light breezes from the east and north-east, it went up to 3000 or 4000 volts. In that place, and in fair weather, I never found the potential other than positive (never negative, never even down to zero), if for brevity we call the earth's potential at the place zero. In perfectly clear weather under a sky sometimes cloudless, more generally somewhat clouded, I often observed the potential at the 9 feet height to vary from about 300 volts gradually to three or four times that amount, and gradually back again to nearly the same lower value in the course of about two minutes.† I inferred that these gradual variations must have been produced by electrified masses of air moving past the place of observation. I did not remark then, but I now see, that the electricity in these moving masses of air must, in all probability have been chiefly positive to cause the variations which I observed, as I shall explain to you a little later.

* Two communications to the Philosophical Society of Glasgow meeting, in the Natural Philosophy Lecture-room of the University of Glasgow, March 27, "On the Electrification of Air": "On the Thermal Conductivity of Rock at different temperatures."

† "Electrostatics and Magnetism" (Sir William Thomson), xvi. §§ 281, 282.

§ 2. Soon after that time a recording atmospheric electrometer * which I devised, to show by a photographic curve the continuous variation of electric potential at a fixed point, was established at the Kew Meteorological Observatory, and has been kept in regular action from the commencement of the year 1861 till the present time. It showed incessant variations quite of the same character, though not often as large, as those which I had observed on the sea-beach of Arran.

Through the kindness of the Astronomer Royal, I am able to place before you this evening the photographic curves for the year 1893, produced by a similar recording electrometer which has been in action for many years at the Royal Observatory, Greenwich. They show, as you see, not infrequently, during several hours of the day or night, negative potential and rapid transitions from large positive to large negative. Those were certainly times of broken weather, with at least showers of rain, or snow, or hail. But throughout a very large proportion of the whole time the curve quite answers to the description of what I observed on the Arran sea-beach thirty-six years ago, except that the variations which it shows are not often of so large amount in proportion to the mean or to the minimums.

§ 3. Thinking over the subject now, we see that the gradual variations, minute after minute through so wide a range as the 3 or 4 to 1, which I frequently observed, and not infrequently rising to twenty times the ordinary minimum, must have been due to *positively* electrified masses of air, within a few hundred feet of the place of observation, wafted along with the gentle winds of 5 or 10 or 15 feet per second which were blowing at the time. If any comparably large quantities of negatively electrified air had been similarly carried past, it is quite certain that the minimum observed potential, instead of being in every case positive, would have been frequently large negative.

§ 4. Two fundamental questions in respect to the atmospheric electricity of fair weather force themselves on our attention:—(1) What is the cause of the prevalent positive potential in the air near the earth, the earth's potential being called zero? (2) How comes the lower air to be electrified to different electric densities whether positive or negative in different parts? Observations and laboratory experiments made within the last six or eight years, and particularly two remarkable discoveries made by Lenard, which I am going to describe to you, have contributed largely to answering the second of these questions.

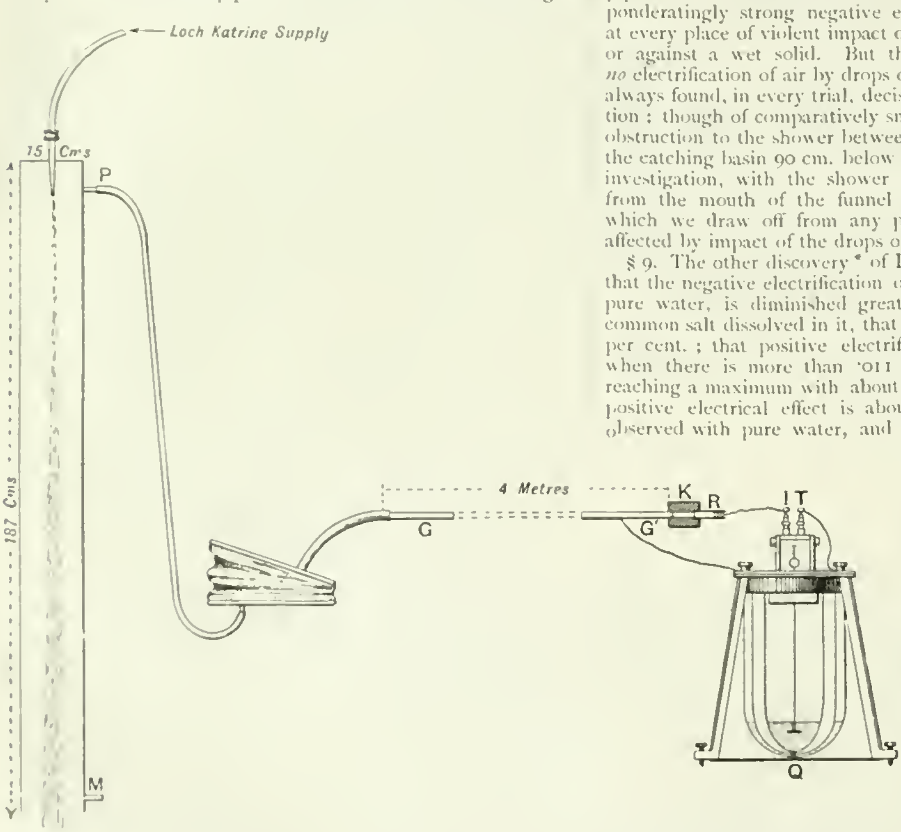
§ 5. In an article "On the Electrification of Air by a Water-jet," by Magnus Maclean and Makita Goto,† experiments were described showing air to be negatively electrified by a jet of water shot vertically down through it from a fine nozzle into a basin of water about 60 centimetres below it. It seemed natural to suppose that the observed electrification was produced by the rush of the fine drops through the air; but Lenard conclusively proved, by elaborate and searching experiments, that it was in reality due chiefly, if not wholly, to the violent commotions of the drops impinging on the water surface of the receiving basin, and he found that the negative electrification of the air was greater when they were allowed to fall on a hard slab of any material thoroughly wetted by water, than when they fell on a yielding surface of water several centimetres deep. He had been engaged in studying the great negative potential which had been found in air in the neighbourhood of waterfalls, and which had generally been attributed to the inductive action of the ordinary fine weather electric force, giving negative electricity to each drop of water-spray before it breaks away from conducting communication with the earth. Before he knew Maclean and Goto's paper, he had found strong reason for believing that that theory was not correct, and that the true explanation of the electrification of the air must be found in some physical action not hitherto discovered. A less thorough inquirer might have been satisfied with the simple explanation of the electricity of waterfalls naturally suggested by Maclean and Goto's result, and might have rested in the belief that it was due to an electrifying effect produced by the rush of the broken water through the air; but Lenard made an independent experimental investigation in the Physical Laboratories of Heidelberg and Bonn, by which he learned that the seat of the negative electrification of the air electrified is the lacerated water at the foot of the fall, or at any rocks against which the water impinges, and not the multitudinous interfaces between air and water falling freely in drops through it.

§ 6. It still seems worthy of searching inquiry to find

* "Electrostatics and Magnetism" xvi. §§ 271, 292.

† *Philosophical Magazine*, 1890, second half-year.

electrification of air by water falling in drops through it, even though we now know that, if there is any such electrification, it is not the main cause of the great negative electrification of air which has been found in the neighbourhood of waterfalls. For this purpose an experiment has been very recently made by Mr. Maclean, Mr. Galt, and myself, in the course of an investigation regarding electrification and diselectrification of air with which we have been occupied for more than a year. The apparatus which we used is before you. It consists of a quadrant electrometer connected with an insulated electric filter * applied to test the electrification of air drawn from different parts of a tinned iron funnel, 187 centimetres long and 15 centimetres diameter, fixed in a vertical position with its lower end open and its upper end closed, except a glass nozzle, of 1·6 mm. aperture, admitting a jet of Glasgow supply water (from Loch Katrine) shot vertically down along its axis. The electric filter (R in the drawing), a simplified and improved form of that described in the *Proceedings* of the Royal Society for March 21, consists of twelve circles of fine wire gauze rammed as close as possible together in the middle of a piece of block tin pipe of 1 cm. bore and 2 cm. length.



One end of it is stuck into one end of a perforation through a block of paraffin, K, which supports it. The other end (G') of this perforation is connected by block tin pipe (which in the apparatus actually employed was 4 metres long, but might have been shorter), and india-rubber tubing through bellows to one or other of two short outlet pipes (M and P) projecting from the large funnel.

§ 7. We first applied the india-rubber pipe to draw air from the funnel at the *upper* outlet, P, and made many experiments to test the electricity given by it to the receiving filter, R, under various conditions as to the water-jet; the bellows being worked as uniformly as the operator could. When the water fell fairly through the funnel with no drops striking it, and through 90 cm. of free air below its mouth, a small negative electrification of R was in every case observed (which we thought might possibly be attributable to electrification of the air where the water was caught in a basin about 90 cm. below the mouth of the funnel). But when the funnel was slanted so that the whole shower of drops from the jet, or even a small part of it, struck the inside of the funnel, the negative electrification of R was largely increased. So it was also when the shower, after falling freely down the middle of the funnel, impinged on a metal plate in metallic communication with the funnel, held close under its mouth, or 10 or 20 cm. below it. For example, in a series of experiments made last Monday (March 25), we found ·28 of a volt in 15 minutes with no obstruction to the shower; and 4·18 volts in five minutes, with a metal plate held three or four centimetres below the mouth of the funnel; the air being drawn from the upper outlet (P). Immediately after, with P closed, and air drawn from the lower outlet (M), but all other circumstances the same, we found ·20 of a volt in five minutes with no obstruction; and 6·78 volts in five minutes with the metal plate held below the mouth as before.

§ 8. These results, and others which we have found, with many variations of detail, confirm, by direct test of air drawn away from the neighbourhood of the waterfall through a narrow pipe to a distant electrometer, Lenard's conclusion that a preponderatingly strong negative electrification is given to the air at every place of violent impact of a drop against a water-surface, or against a wet solid. But they do not prove that there is *no* electrification of air by drops of water falling through it. We always found, in every trial, decisive proof of negative electrification; though of comparatively small amount when there was no obstruction to the shower between the mouth of the funnel and the catching basin 90 cm. below it. We intend to continue the investigation, with the shower falling freely far enough down from the mouth of the funnel to make quite sure that the air which we draw off from any part of the funnel is not sensibly affected by impact of the drops on anything below.

§ 9. The other discovery * of Lenard, of which I told you, is that the negative electrification of air, in his experiments with pure water, is diminished greatly by very small quantities of common salt dissolved in it, that it is brought to nothing by ·011 per cent.; that positive electrification is produced in the air when there is more than ·011 per cent. of salt in the water, reaching a maximum with about 5 per cent. of salt, when the positive electrical effect is about equal to the negative effect observed with pure water, and falling to 14 per cent. of this amount when there is 25 per cent. of salt in the solution. Hence sea-water, containing as it does about 3 per cent. of common salt, may be expected to give almost as strong positive electrification to air as pure water would give of negative in similar circumstances as to commotion. Lenard infers that breaking waves of the sea must give positive electricity to the air over them; he finds, in fact, a recorded observation by Exner, on the coast of Ceylon, showing the normal positive electric potential of the air to be notably increased by a storm at sea. I believe Lenard's discovery fully explains also some very interesting observations of atmospheric electricity of my own, which I described in a letter to Dr. Joule, which he published in the *Proceedings* of the Literary and Philosophical Society of Manchester for October 18, 1859.† "The atmospheric effect ranged from 30° to about 420° [of a heterostatic torsion electrometer of 'the divided-ring' species] during the four days which I had to test it; that is to say, the electrometric force per foot of air, measured horizontally from the side of the house, was from 9 to above 126 zinc-copper water cells. The weather was almost perfectly settled, either calm, or with slight east wind, and in general an easterly haze in the air. The electrometer twice within half an hour went above 420°, there being at the time a fresh temporary breeze from the east. What I had previously observed regarding the effect of east wind was amply confirmed.

* Kelvin, Maclean, Galt, "On the Diselectrification of Air." *Proc.* Roy. Soc. March 14, 1895.

* "Ueber die Electricitat der Wasserfälle." Table xvii. p. 628. *Annalen der Physik und Chemie*, 1892, vol. xlvi.

† Republished in "Electrostatics and Magnetism." "Atmospheric Electricity," xvi. § 262.

Invariably the electrometer showed very high positive in fine weather, before and during east wind. It generally rose very much shortly before a slight puff of wind from that quarter, and continued high till the breeze would begin to abate. I never once observed the electrometer going up unusually high during fair weather without east wind following immediately. One evening in August I did not perceive the east wind at all, when warned by the electrometer to expect it; but I took the precaution of bringing my boat up to a safe part of the beach, and immediately found by waves coming in that the wind must be blowing a short distance out at sea, although it did not get so far as the shore. . . . On two different mornings the ratio of the house to a station about sixty yards distant on the road beside the sea was ·97 and ·96 respectively. On the afternoon of the 11th instant, during a fresh temporary breeze of east wind, blowing up a little spray as far as the road station, most of which would fall short of the house, the ratio was 1·08 in favour of the house electrometer—both standing at the time very high—the house about 350°. I have little doubt but that this was owing to the negative electricity carried by the spray from the sea, which would diminish relatively the indications of the road electrometer."

§ 10. The negative electricity spoken of in this last sentence, "as carried by the spray from the sea," was certainly due to the inductive effect of the ordinary electrostatic force in the air close above the water, by which every drop or splash breaking away from the surface must become negatively electrified; but this only partially explains the difference which I observed between the road station and the house station. We now know, by the second of Lenard's two discoveries, to which I have alluded, that every drop of the salt water spray, falling on the ground or rocks wetted by it, must have given positive electricity to the adjoining air. The air, thus positively electrified, was carried towards and over the house by the on-shore east wind which was blowing. Thus, while the road electrometer under the spray showed less electrostatic force than would have been found in the air over it and above the spray, the house electrometer showed greater electrostatic force because of the positively electrified air blown over the house from the wet ground struck by the spray.

§ 11. The strong positive electricity, which, as described in my letter to Joule, I always found in Arran with east wind, seemed at first to be an attribute of wind from that quarter. But I soon found that in other localities east wind did not give any very notable augmentation, nor perhaps any augmentation at all, of the ordinary fair weather positive electric force, and for a long time I have had the impression that what I observed in this respect, on the sea-beach of Brodick Bay in Arran, was really due to the twelve nautical miles of sea between it and the Ayrshire coast east-north-east of it; and now it seems to me more probable than ever that this is the explanation when we know from Lenard that the countless breaking waves, such as even a gentle east wind produces over the sea between Ardrossan and Brodick, must every one of them give some positive electricity to the air wherever a spherule of spray falls upon unbroken water. It becomes now a more and more interesting subject for observation (which I hope may be taken up by naturalists having the opportunity) to find whether or not the ordinary fine weather positive electric force at the sea coast in various localities is increased by gentle or by strong winds from the sea, whether north, south, east or west of the land.

§ 12. From Lenard's investigation we now know that every drop of rain falling on the ground or on the sea,* and every drop of fresh water spray of a breaking wave, falling on a fresh water lake, sends negative electricity from the water surface to the air; and we know that every drop of salt water, falling on the sea from breaking waves, sends positive electricity into the air from the water surface. Lenard remarks that more than two-thirds of the earth's surface is sea, and suggests that breaking sea-waves may give contributions of positive electricity to the air which may possibly preponderate over the negative electricity given to it from other sources, and may thus be the determining cause of the normal fair weather positive of natural atmospheric electricity. It seems to me highly probable that this preponderance is real for atmospheric electricity at sea. In average weather, all the year round, sailors in very small vessels are more wet by sea-spray than by rain, and I think it is almost certain that more positive electricity is given to the air by breaking waves than negative electricity by rain. It seems also probable that the positive electricity from the waves is much more carried up by strong winds to considerable heights above the sea, than the negative electricity given to the air by rain falling on the sea; the greater part of which may be quickly lost into the sea, and but a small part carried up to great heights. But it seems to me almost certain that the exceedingly rapid recovery of the normal fair weather positive, after the smaller positive or the negative atmospheric electricity of broken weather, which was first found by Beccaria in Italy 120 years ago, and which has been amply verified in Scotland and England,* could not be accounted for by positively electrified air coming from the sea. Even at Beccaria's Observatory, at Garzegna di Mondovi in Piedmont, or at Kew, or Greenwich, or Glasgow, we should often have to wait a very long time for reinstatement of the normal positive after broken weather, if it could only come in virtue of positively electrified air blowing over the place from the sea; and several days, at least, would have to pass before this result could possibly be obtained in the centre of Europe.

§ 13. It has indeed always seemed to me probable that the rain itself is the real restorer of the normal fair weather positive. Rain or snow, condensing out of the air high-up in the clouds, must itself, I believe, become negatively electrified as it grows, and must leave positive electricity in the air from which it falls. Thus rain falling from negatively electrified air would leave it less negatively electrified, or non-electrified or positively electrified: rain falling from non-electrified air would leave it positively electrified; and rain falling from positively electrified air would leave it with more of positive electricity than it had before it lost water from its composition. Several times within the last thirty years I have made imperfect and unsuccessful attempts to verify this hypothesis by laboratory experiments, and it still remains unproved. But I am much interested just now to find some degree of observational confirmation of it in Elster and Geitel's large and careful investigation of the electricity produced in an insulated basin by rain or snow falling into it, which they described in a communication published in the *Sitzungsberichte* of the Vienna Academy of Sciences, of May 1890. They find generally a large electrical effect, whether positive or negative, by rain or snow falling into the basin for even so short a time as a quarter of a minute, with however, on the whole, a preponderance of negative electrification.

§ 14. But my subject this evening is not merely natural atmospheric electricity, although this is certainly by far the most interesting to mankind of all hitherto known effects of the electrification of air. I shall conclude by telling you very briefly, and without detail, something of new experimental results regarding electrification and diselectrification of air, found within the last few months in our laboratory here by Mr. Maclean, Mr. Galt, and myself. We hope before the end of the present session of the Royal Society to be able to communicate a sufficiently full account of our work.

§ 15. Air blown from an uninsulated tube, so as to rise in bubbles through pure water in an uninsulated vessel, and carried through an insulated pipe to the electric receiving filter, of which I have already told you, gives negative electricity to the filter. With a small quantity of salt dissolved in the water, or sea water substituted for fresh water, it gives positive electricity to the air. There can be no doubt but these results are due to the same physical cause as Lenard's negative and positive electrification of air by the impact of drops of fresh water or of salt water on a surface of water or wet solid.

§ 16. A small quantity of fresh water or salt water shaken up vehemently with air in a corked bottle electrifies the air, fresh water negatively, salt water positively. A "Winchester quart" bottle (of which the cubic contents is about two litres and a half), with one-fourth of a litre of fresh or salt water poured into it, and closed by an india-rubber cork, serves very well for the experiment. After shaking it vehemently till the whole water is filled with fine bubbles of air, we leave it till all the bubbles have risen and the liquid is at rest, then take out the cork, put in a metal or india-rubber pipe, and by double-acting bellows, draw off the air and send it through the electric filter. We find the electric effect, negative or positive according as the water is fresh or salt, shown very decidedly by the quadrant electrometer: and this, even if we have kept the bottle corked for two or three minutes after the liquid has come to rest before we take out the cork and draw off the air.

§ 17. An insulated spirit lamp or hydrogen lamp being con-

* "Ueber die Electricität der Wasserfälle." *Annalen der Physik und Chemie*, 1892, vol. xlvi. p. 631.

* "Electrostatics and Magnetism," xvi. § 287.

nected with the positive or with the negative terminal of a little Voss electric machine, its fumes (products of combustion mixed with air) sent through a block-tin pipe, four metres long, and one centimetre bore, ending with a short insulating tunnel of paraffin and the electric filter, gives strong positive or strong negative electricity to the filter.

§ 18. Using the little biscuit-canister and electrified needle, as described in "our communication" * to the Royal Society "On the Diselectrification of Air," but altered to have two insulated needles with varied distances of from half a centimetre to two or three centimetres between them, we find that when the two needles are kept at equal differences of potential positive and negative, from the enclosing metal canister, little or no electrification is shown by the electric filter; and when the differences of potential from the surrounding metal are unequal, electrification, of the same sign as that of the needle whose difference of potential is the greater, is found on the filter.

When a ball and needle-point are used, the effect found depends chiefly on the difference of potentials between the needle-point and the surrounding canister, and is comparatively little affected by opposite electrification of the ball. When two balls are used, and sparks in abundance pass between them, but little electricity is deposited by the sparks in the air, even when one of the balls is kept at the same potential as the surrounding metal. [The communication was illustrated by a repetition of some of the experiments shown on the occasion of a Friday evening lecture † on Atmospheric Electricity at the Royal Institution on May 18, 1860, in which one half of the air of the lecture-room was electrified positively, and the other half negatively, by two insulated spirit lamps mounted on the positive and negative conductors of an electric machine.]

(2) "ON THE THERMAL CONDUCTIVITY OF ROCK AT DIFFERENT TEMPERATURES."

Experiments by Lord Kelvin and Mr. Erskine Murray were described, and the apparatus used in them was shown, by which it was found that the thermal conductivity of specimens of slate, sandstone, and granite is less at higher temperatures than at lower for each of these rocks. The last tested was Aberdeen granite, for which experiments of fairly satisfactory accuracy showed the mean conductivity for the range from 146° C. to 215 C. to be 86 per cent. of the mean conductivity in the range from 81 C. to 146 C. They hope to send a communication to the Royal Society describing their work before the end of the present session.

KELVIN.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. D. R. Pike, of the Charterhouse, has been elected to an open Exhibition in Natural Science at Jesus College, and Mr. L. C. W. Brigstocke, of Haverfordwest Grammar School, has been elected to a Welsh Foundation Scholarship in Natural Science at the same College.

Open Scholarships and Exhibitions in Natural Science have been announced for competition at Merton College, New College, Magdalen College, and Corpus Christi College. Particulars may be obtained on application to the Dean in any of these Colleges.

CAMBRIDGE.—The Walsingham Medal for an original monograph on a botanical, geological, zoological, or physiological subject will be awarded in the Michaelmas Term. Essays are to be sent to Prof. Newton by October 10, 1895. Candidates must be B.A.'s not of standing to take the M.A. degree.

The subject for the Adams Prize of 1897 is connected with Bessel's Functions. It is set forth in the *University Reporter* for May 14. The prize is of the value of about £197. It is open to all graduates of the University. Essays are to be sent to the Vice-Chancellor by December 16, 1896.

THE Association of Technical Institutions has endeavoured to induce the Science and Art Department to discontinue the examinations now held in practical inorganic and organic chemistry, and to award attendance grants for instruction in those subjects, the amount of such grants to be dependent upon the report of the Department's inspectors on the efficiency of the equipment and teaching. The Association has received a reply to the effect that it is not possible for the Department to comply with their request. A new syllabus for practical inorganic chemistry will appear, however, in the forthcoming edition of the Science and Art Directory, and there seems little doubt that the instruction will be so arranged in it as to make it possible to coordinate more closely the laboratory and lecture work in that subject, and afford the same latitude to teachers as is given by the new Regulations for Organised Science Schools.

* *Proceedings of the Royal Society*, March 14, 1895.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xvii. No. 2 (Baltimore, April 1895).—A method for calculating simultaneously all the roots of an equation, is a paper by Dr. E. McClintock, which was read before the American Mathematical Society on August 14 and October 27, 1894. It opens with the application to an example employed by Spitzer and by Jelinek. The calculations of these mathematicians can only be done for a pair of roots at a time, and that with considerable difficulty. The method employed by our author is fairly facile. Very little has hitherto been done in the direction of this memoir, which is one of great value in the subject of algebraic equations. The writer discusses eleven examples at length, the highest degreed equation being one of the sixth degree in x.—Sur le logarithme de la fonction gamma, by Hermite, is a note upon Raabe's integral, in continuation of an article in the *Math. Annalen* (41, p. 581).—Sur la pression dans les milieux diélectriques ou magnétiques, by Prof. P. Duhem, corrects an error in his "Leçons sur l'Electricité et le magnétisme," and is a valuable working out of the theory of the pressures, initiated by Clerk Maxwell, and further improved by von Helmholtz, Kirchhoff, and other writers. The number closes with an article on ternary substitution-groups of finite order which leave a triangle unchanged, by H. Maschke. This paper is complementary to C. Jordan's "Sur les équations, differentielles linéaires à integrale algébrique," and "Sur la détermination des groupes d'ordre fini contenues dans le groupe linéaire."

Zeitschrift für wissenschaftliche Zoologie, Bd. lix. Heft 1.—Prof. A. R. von Heider gives a detailed description of a new Actinian (*Zoanthus chierchiae*) obtained during the cruise of the *Vettor Pisani*. Prof. A. Korotneff describes the embryonic development of *Salpa democratica*. According to him the follicle-cells do not play the important part in the development of *Salpa* which Salensky attributed to them, nor do they form a temporary scaffolding for the blastomeres, as stated by Brooks. The embryo is built up of blastomeres in the normal manner, and embryonic layers are present with the same significance as in other groups. The cloaca is formed by the union of endodermal diverticula, and the pericardium develops as an outgrowth of the pharynx.—Prof. W. Schimkewitsch writes upon the structure and development of a species of *Dinophilus* living in the White Sea, near the Solovetzki laboratory. The twofold affinities of this interesting type, on the one hand with the Annelids, and on the other with the Rotifers, are succinctly stated.—Prof. Vejdovsky writes upon the sexual apparatus of *Lumbriculus variegatus*.—Dr. Montgomery deals fully with the anatomy of a new type of Nemertine (*Stichostemma Eilhardi*) discovered in fresh-water aquaria in the Berlin Zoological Institute.—Dr. McKim describes the nephridial funnel apparatus of *Hirudo*.

SOCIETIES AND ACADEMIES.

EDINBURGH.

Royal Society, March 18.—The Rev. Prof. Flint, Vice-President, in the chair.—Prof. Crum-Brown communicated a paper, by Mr. R. Fairbairn and himself, on the action of sodium mercaptide on dibromomalonic ether.—Prof. J. C. Ewart communicated a paper, by Mr. F. J. Cole and himself on the dorsal branches of the cranial and spinal nerves in elasmobranchs.—Dr. Traquair read a paper on phosphorescent sandstones.—Prof. Tait read a note on the electromagnetic wave-surface.

April 1.—Sir Douglas Maclagan, President in the chair.—A paper, by the Duke of Argyll, on the glaciation of two glens, was read. The glens are Glenaray and Glenshira. The usual explanation of the phenomena of glaciation as observed in the West Highlands is that the glaciation was caused by an enormous ice-cap covering the whole country. His Grace does not consider that the phenomena can be so explained. Rocks are found which are striated and smoothed on one side, while the other side remains rough. Isolated blocks, without striation,

are found in positions where they could not have been placed except by the agency of floating ice-floes. He considers that the marks of glaciation were caused by ice-floes, driven by strong north-east and south-west currents, in a sea whose surface reached a level on the land of from 1500 to 2000 feet over the present level. The two glens run nearly parallel in a north-easterly direction, and are separated by a range of hills and moors not much more than two miles broad. The rocks of both belong to the same geological formation, and yet the glens are entirely dissimilar in appearance. Glenshira has smooth, regular slopes, with a smooth level bottom; Glenaray is a typical highland glen traversed by a rapid river with a rocky bed and three waterfalls, and exhibits strong glaciation. His Grace does not consider that an ice-sheet, operating over the whole country, could account for these differences. Neither does he consider that local glaciers could have produced the effect, for such a glacier must have been formed on the slopes of Ben Loy and have flowed down Glenshira. On the other hand, Glenaray terminates in a low pass 480 feet above sea-level, while Glenshira is closed in by ridges 2000 feet in height. The former was therefore open to the action of floes, while the higher peaks would shelter the latter.

April 17.—Sir Douglas Maclagan, President, in the chair. Prof. Flinders Petrie gave a lecture "On a New Race in Egypt," describing the result of his work in Egypt during the last season.

PARIS.

Academy of Sciences, May 6.—M. Marey in the chair.—The zoological work of James Dana, by M. Blanchard. The main outlines of James Dana's work are sketched from a zoologist's point of view. Reference is particularly made to his work on the geographical distribution of zoophytes, on coral reefs and islands, on animal distribution with reference to depth and temperature in the sea, and on Crustaceans.—The mineralogical and geological work of James Dana, by M. Daubrée. A very full account is given of the chief points in Dana's geological work, special reference being made to his publication of a "System of Mineralogy," and his "Manual of Geology."—The work of M. Carl Vogt, by M. Émile Blanchard.—Researches on the cerite earths, by M. P. Schützenberger. The author establishes the result that in cerite, cerium oxide is accompanied by small quantities of another earth of a metal with somewhat lower atomic weight, which is capable of being oxidised like cerium oxide, and of which the sulphate is isomorphous with that of cerium, and gives insoluble double sulphates with alkaline sulphates. The calcined higher oxide is of reddish-brown colour, even without presence of didymium.—Action of fluorine on argon, by M. Henri Moissan (see Notes, p. 61). Systematic application of the potato to the feeding of cattle, by M. Aimé Girard. The results are reported of experiments on the feeding of cattle and sheep, both quantity and quality of meat obtained being considered. The best results were obtained with given proportions of cooked potatoes and hay, a very superior article being obtained yielding high profits.—Report on the table of triangular numbers of M. Arnaudeau.—On the orbit of the 1771 comet, by M. Bigourdan. A re-examination of the original manuscript of Saint-Jacques has allowed the discovery of an error made by Burckhardt in reducing observations of this comet. The result of a preliminary recalculation of the observations allows the definite rejection of a hyberbolic orbit, and renders it very probable that the orbit is an ellipse of eccentricity 0·998.—Every algebraical condition imposed on the movement of a body is realisable by means of an articulated system, by M. G. Kœnigs.—On the use of a fourth dimension, by M. de la Rive.—On fluted spectra, by Prof. Arthur Schuster. A discussion of the different interpretation of phenomena by the author and M. Poincaré. In conclusion, the author is unable to doubt the justice of M. Gouy's view, that the regularity of the vibrations, shown by the observations of Fizeau and Foucault, does not exist in the luminous movement, but is produced by the apparatus used.—Unequal absorption of dextrorotatory and lævorotatory circularly polarised light in certain active substances, by M. A. Cotton. This unequal absorption is indicated by the conversion of a plane polarised ray into an elliptically polarised ray by passage through substances such as the coloured metallic tartrates. The method of measuring the effect is indicated and results promised in a further communication.—On the freezing of solutions at constant temperature, by M. Sarrau. Solidification is produced under pressure so that no lowering of the freezing point occurs, the connection between the compensating pressure and molecular weight is considered.—Closed isothermal cycles, reversible and maintained in equilibrium by gravity, by M. A. Ponsot.—Observations on the project of a balloon expedition to the Arctic regions put forth by M. S. A. Andrée, by M. Gaston Tissandier.—Researches on mercurous sulphate, nitrate, and acetate, by M. Raoul Varet. The heats of formation from their elements taken in their actual states are: for $Hg_2 SO_4$ sol. + 175 Cal.; for $Hg_2 (NO_3)_2 2H_2O$ sol. + 69·4 Cal.; and for $Hg_2 (C_2H_3O_2)_2$ sol. + 202·1 Cal.—On the presence of chitin in the cellular membrane of mushrooms, by M. Eugene Gilson. Chitin has been found in all the fungi examined, taking the place and fulfilling the functions of cellulose in phanerogams and cryptogams. The experimental evidence concerns Agaricus campestris, Amanita muscaria, Cantharellus cebarius, Hypholoma fasciculare, Polyporus officinalis, Polyporus fumosus, Russula, Boletus, Tricholona, Bovista, and Claviceps purpurea.—Comparative study of the "appareils odorifiques" in the different groups of Heteropterous Hemiptera, by M. J. Künckel d'Herculais.—Overlap of the Jurassic beds in the massif of the Vendée, by M. Fred. Wallerant.—Influence of de-oxygenated blood, and of some poisons, on the contractility of the lymphatic vessels, by MM. L. Camus and E. Gley.—On the scarlatinous streptococcus, by M. Ad. d'Espine.—The manuring of vines and quality of the wines, by M. A. Müntz. The supposed deleterious action of manure on the quality of wine produced from the dressed vineries has no substantial foundation in fact.

BERLIN.

Physiological Society, April 5.—Prof. H. Munk, President, in the chair.—Prof. J. Munk had investigated the excretion of mineral waste during Prof. Zuntz' experiments on the effects of excessive exercise on metabolism. (See NATURE, vol. li. p. 503.) He found that the urinary output of sulphur was increased in correspondence with the increased proteid metabolism, the excess taking the form of sulphuric acid, not of ethereal-sulphates. Phosphorus and potassium were also similarly increased, and since neither of them are normal constituents of proteid, their greater excretion denoted some destruction of other tissues. This view was confirmed by the increased excretion of lime, which further points to a possibly greater metabolism of bone-tissue during the exercise.—Dr. Treitel had carried out observations on the perception of the vibrations of tuning-forks by the skin, and had found that the sensibility varied in different parts of its surface, and did not correspond with that for the perception of mere touch or localisation.—Dr. Schultz demonstrated the contraction of single bundles of unstriated muscle-fibres on a preparation made from the muscular coat of a frog's stomach. The fibres could be seen to slowly contract on electric stimulation, relaxing equally slowly after the stimulus had ceased.

Meteorological Society, April 2.—Prof. Hellmann, President, in the chair.—Dr. Less spoke on the various types of winter weather, dealing in detail with the five types established by Teisserenc de Bort as depending on the distribution of barometric maxima and minima over the Atlantic Ocean and Europe. He added to these a sixth type of mild and squally weather which most usually follows after other types of warm winter weather. He pointed out that the winter just past could for the most part not be included under any of the above six types.

Physical Society, April 26.—Prof. Schwalbe, President, in the chair.—Dr. Pringsheim gave an account of his experiments on the electric conductivity of heated gases. In a Chamotte-tube closed by brass caps the various gases, such as air, hydrogen, and carbon dioxide, were heated to a temperature of 700 to 900° C. The electrodes consisted of circular discs of platinum capable of being placed at varying distances from each other. A current of 1·6 to 10 volts was passed through the gases, and all the results obtained by Becquerel in 1853 were confirmed. As the electrodes were separated from each other the deflection of the galvanometer became less, and with constant distance between the electrodes the current became less the longer it flowed. This fact led to the suspicion, verified by experiment, that polarisation was here playing a part. On breaking the primary current, the polarisation of the electrodes was quite perceptible for a full half-hour. The speaker concluded from the above that conduction in heated gases is an electrolytic phenomenon, and intends to carry on his researches, using more carefully purified gases and a trustworthy pyrometer.—Dr. du Bois reported on a paper presented by Prof. van Aubel, dealing with Hall's phenomenon as investigated on thin layers of bismuth

deposited electrolytically. It appeared that when the deposit was made from nitrate of bismuth the phenomenon was as marked as it is with cast plates of the metal, whereas when deposited from the tartrate the phenomenon was either extremely feeble or non-existent. The asymmetry of the phenomenon on reversal of the magnetic field was explained by the author as due to the influence exerted by the magnetic field on the electric conductivity of the metal. He further regarded the difference in behaviour of the metallic film as precipitated, on the one hand, from the nitrate, and on the other, from the tartrate or citrate, as due to the fact that in the case of the latter salts the bismuth is mixed with carbon, whereas in the case of the nitrate the metal is deposited in a pure state.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, MAY 16.

ROYAL SOCIETY, at 4.30.—On Measurements of Small Strains in the Testing of Materials and Structures: Prof. Ewing, F.R.S.—The Electrical Measurement of Starlight. Observations made at the Observatory of Daramona House, Co. Westmeath, in April 1895. Preliminary Report: Prof. G. M. Minchin.—The Complete System of the Periods of a Hollow Vortex Ring: H. C. Pocklington.—India's Contribution to Geodesy: General Walker, F.R.S.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—Kjeldahl's Process for the Determination of Nitrogen; Dr. Bernard Dyer.—The Action of Nitrous Acid on 1 : 4 : 2 Dibromaniline: Prof. Meldola, F.R.S., and E. R. Andrews.—Derivatives of Succinyl and Phthalyl Dithiocarbimides: Prof. Dixon and Dr. Doran.

ROYAL INSTITUTION, at 3.—The Liquefaction of Gases: Prof. J. Dewar, F.R.S.

SOCIETY OF ANTIQUARIES, at 8.30.

FRIDAY, MAY 17.

QUEKETT MICROSCOPICAL CLUB, at 8.

EPIDEMIOLOGICAL SOCIETY.—Paper by Dr. Washbourn.

SATURDAY, MAY 18.

LONDON GEOLOGICAL FIELD CLASS (Cannon Street Station), at 2.17.—Excursion to view Escarpment Valleys from the Weald to Chalk.

GEOLOGISTS' ASSOCIATION (Cannon Street Station), at 1.35.—Excursion to Betchworth and Headley.

ESSEX FIELD CLUB (Chingford, 2 p.m., and High Beach, 4 p.m.).—Inspection of Forest, and Paper by Mr. E. N. Buxton, on Plan for forming a Protected Area for certain Birds in Old Waltham Forest District.

MONDAY, MAY 20.

SOCIETY OF ARTS, at 8.—Japanese Art Industries: Dr. Ernest Hart.

ROYAL GEOGRAPHICAL SOCIETY, at 8.45.—Meeting to Commemorate the Fiftieth Anniversary of the Sailing of the Arctic Expedition under Sir John Franklin.

VICTORIA INSTITUTE, at 4.30.—Prof. E. Hull, F.R.S.

MEDICAL SOCIETY, at 8.30.

TUESDAY, MAY 21.

ROYAL INSTITUTION, at 3.—Thirty Years' Progress in Biological Science (II.): Prof. E. Ray Lankester, F.R.S.

SOCIETY OF ARTS, at 8.—Commercial Education in Belgium: Prof. William Layton.

ZOOLOGICAL SOCIETY, at 8.30.—On the Ornithological Collections made by Dr. Donaldson Smith during his Recent Expedition in Somaliland and Gallaland: Dr. R. Bowdler Sharpe.—A Synopsis of the Genera and Species of Apodal Batrachians, with Descriptions of a New Genus and Species (Bdellophis vittatus): G. A. Boulenger, F.R.S.—List and Distribution of the Land-Mollusca of the Andaman and Nicobar Group of Islands in the Bay of Bengal, with Descriptions of some New Species: Lieut.-Colonel H. H. Godwin-Austen, F.R.S.—On a New Species of Hedgehog from Somaliland: Dr. J. Anderson, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Last Ballot for Members for the Session.

ROYAL STATISTICAL SOCIETY (Royal United Service Institution), at 5.—Municipal Finance: E. Orford Smith.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Apparatus for Process Photography: Wm. Gamble.

ROYAL VICTORIA HALL, at 8.—The History of a Myth: Prof. Sollas, F.R.S.

PATHOLOGICAL SOCIETY, at 8.30.

WEDNESDAY, MAY 22.

SOCIETY OF ARTS, at 8.—The Dressing and Metallurgical Treatment of Nickel Ores: A. G. Charleton.

GEOLOGICAL SOCIETY, at 8.—On a Human Skull and Limb-Bones found in the Palæolithic Terrace-Gravel at Galley Hill (Kent): E. T. Newton, F.R.S.—Geological Notes of a Journey round the Coast of Norway and into Northern Russia: G. S. Boulger.—On Rhætic Foraminifera from Wedmore (West Somerset): Frederick Chapman.

THURSDAY, MAY 23.

ROYAL INSTITUTION, at 3.—The Instruments and Methods of Spectroscopic Astronomy: Dr. W. Huggins, F.R.S.

SOCIETY OF ARTS, at 4.30.—The Northern Balochis: their Customs and Folk-lore: Oswald V. Yates.

INSTITUTION OF ELECTRICAL ENGINEERS (Society of Arts), at 8.—On the Recent Development of the Single-Acting High-Speed Engine, for Central Station Work: Mark H. Robinson.

FRIDAY, MAY 24.

ROYAL INSTITUTION, at 9.—The Absolute Measurement of Electrical Resistance: J. Viriamu Jones, F.R.S.

LINNEAN SOCIETY, at 3.—Annual Meeting.

PHYSICAL SOCIETY, at 5.—On Mixtures of Ethane and Nitrous Oxide: Dr. Kuenen.—The Measurement of Cyclically Varying Temperature: H. F. W. Burstall.

SATURDAY, MAY 25.

GEOLOGISTS' ASSOCIATION (Paddington Station), at 10.2 a.m.—Excursion to Goring. Directors: J. H. Blake and W. Whitaker, F.R.S.

LONDON GEOLOGICAL FIELD CLASS (Waterloo Station), at 3.5.—Excursion to the Bagshot Sand Hills at Frimley.

ROYAL BOTANIC SOCIETY, at 3.45.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Æsthetic Principles: H. R. Marshall (Macmillan).—Crystallography: Prof. N. Story-Maskelyne (Oxford, Clarendon Press).—A Primer of Mayan Hieroglyphics: Dr. D. G. Brinton (Boston, Ginn).—The Migration of British Birds: C. Dixon (Chapman).—Electricity in our Homes and Workshops: S. F. Walker, 3rd edition (Whittaker).—The Practical Telephone Handbook, J. Poole, 2nd edition (Whittaker).—The Land Birds in and around St. Andrews: G. Bruce (Dundee, Leng).—Wild Nature won by Kindness: Mrs. Brightwen, 6th edition (Unwin).—The Elements of Botany: F. WERNER VON SIEMENS.

The Scientific and Technical Papers of Werner von Siemens. Translated from the second German edition. Two volumes. (London: John Murray, 1892 and 1895.)

THESE two large volumes form a complete history of the work of Werner Siemens, and give a very vivid impression of his unceasing activity. In addition to building up one of the largest commercial houses on the continent, and by his inventions and discoveries materially assisting in almost every step which, during the last fifty years, has been made in the application of electricity to the service of man, he has found time to conduct long researches on subjects unconnected with his technical work, and, particularly in his later years, has written several important papers on meteorology. It is chiefly, however, in connection with electro-technology that the name of Siemens is famous, for it is this subject that Werner Siemens in Germany, and Sir William Siemens in England, have made particularly their own.

The first of the volumes under notice contains the "scientific" papers, while the second contains the technical ones; the papers in either volume being arranged in chronological order. The distinction drawn between the scientific and technical papers is more apparent than real, for in most of the papers included under the first of these heads it is very evident that the investigations were suggested by some difficulty met with in practice, or were undertaken with a view to some practical application. Hence it is questionable whether it would not have been better to keep all the papers together, arranging them in chronological order, so as to render the relation between the experimental or theoretical investigation and its practical application more obvious.

The first paper in chronological order is a note on "an application by Second-Lieutenant Werner Siemens for a patent for a process of dissolving gold by means of the galvanic current, and for gilding by the wet method." Although no complete account is given of the method employed, this note is of interest for two reasons. In the first place, the experiments which led to the discovery of this method of electro-gilding were made in a cell at the citadel of Magdeburg, in which place, on account of his participation in a duel, young Siemens was at the time a prisoner; the chemicals and apparatus employed being procured and smuggled into the fortress by a friendly chemist of the town. In the second place, it was the sale of the patent rights in this invention in England which supplied the brothers Werner and William with the necessary funds to carry on their experiments, and so helped to lay the foundation of the important firms of Siemens and Halske in Germany, and Siemens Bros. in England.

Although still in the army, Werner Siemens continued his scientific experiments, the next discovery of importance having reference to the insulation of electric wires with gutta-percha. When the newly-discovered substance, gutta-percha, was first put upon the English market, William Siemens sent a specimen to his brother, who, being at that time engaged in an attempt to discover a practicable method of insulating underground telegraph wires, immediately proceeded to try if this substance was suitable for the purpose, and found that even a thin layer when freed from moisture possessed sufficient insulating power. In addition, the property which gutta-percha possesses of becoming plastic and sticking together when heated, appeared to remove the difficulty of making sound joints between the separate pieces of the covering. At first a hot gutta-percha strip was pressed round the wire by means of grooved rollers, and cables insulated in this way were used on a short underground telegraph line between Berlin and Gross-Beeren, as well as for the submarine mines, the first of their kind, which Siemens laid down for the defence of Kiel harbour. It was found, however, that the method of covering was defective, since the material rolled round the wire often did not stick well together. In order to overcome this difficulty, Siemens, in conjunction with his future partner, Halske, invented a machine by means of which gutta-percha could be continuously pressed round the wire without any seam. The plastic gutta-percha is in this machine forced into a metal box having a number of holes drilled through two opposite sides: the holes on the lower side being of such a size as to just allow the passage of the uncovered wire, while the holes on the upper side are the size of the finished insulated wire. The wires pass through the lower narrow holes into the space filled with hot gutta-percha, and come out through the upper holes covered with a uniform and seamless coating.

In consequence of the perfection with which wires could be insulated by this new method, Siemens was employed in designing and laying the Prussian State telegraphs, and in this connection devised a method for testing the perfection of the insulation during the manufacture of the cable, and also a system of tests for localising the position of any "faults" which might occur after the cable was buried in the ground. While superintending the laying of the Red Sea cable, these systematic tests were further elaborated by Siemens, and the success which attended the laying of this cable, as well as the numerous others laid by his firm, may be traced in a great measure to the severe and continuous testing to which the cables were subjected during the process of manufacture and the subsequent laying.

In practically all the earlier telegraph lines of the Prussian telegraphs, underground conductors were employed, since Siemens considered they were better than overhead conductors, being less liable to malicious or accidental injury. In addition, they are unaffected by the atmospheric electricity, which in a dry climate often renders the overhead lines unworkable. Although these underground lines were in after years a source of constant trouble, on account of the frequent break-downs, attributed by Siemens to careless and defective repairing, yet their use led him to two very interesting discoveries. In the first place, he found that an underground cable acted like a large Leyden jar, the copper conductor forming the inside, and the moist earth the outside coating. On this account, it was found necessary to design special apparatus to work satisfactorily through these underground lines, and the practice obtained in designing such instruments must have stood him in good stead when he

 E

came to deal with submarine cables, in which the same capacity effect is met with. The second point was the observation that very strong earth currents—that is, electric currents through the crust of the earth—were produced whenever the aurora borealis was visible.

There is one paper which, although it is included in the first volume, certainly describes a rather amusing practical application of electricity. Werner Siemens, with a party of friends, had ascended the Cheops pyramid, and after reaching the top they noticed that the wind, which had been continually increasing in strength, was raising the sand of the desert with a continuous whirling motion. "When it had arrived at the highest step we noticed a whistling noise, which I ascribed to the increasing violence of the wind. The Arabs, who were squatted around us on the nearest steps, sprang up suddenly with the cry 'Chamsin,' and held up their forefinger in the air. There was now a peculiar whistling noise to be heard, similar to that of singing water. We thought at first that the Arabs were uttering this sound, but I soon satisfied myself that it also took place when I stood upon the highest point of the pyramid and held up my own forefinger in the air. There was also a slight, hardly perceptible, prickling observable on the skin of the finger which was opposed to the wind. I could only explain this fact, observed by all of us, as an electrical phenomenon, and such it proved to be. When I held up a full bottle of wine, the top of which was covered with tinfoil, I heard the same singing sound as when the finger was held up. At the same time little sparks sprang continually from the label to my hand, and when I touched the head of the bottle with my other hand, I received a strong electric shock. It is clear that the liquid inside the bottle, brought into metallic connection with the metallic covering of the head of the bottle through the damp cork, formed the inner coating of a Leyden jar, whilst the label and hand formed the outer coating. When I had completed the outer coating of my bottle by wrapping it in damp paper, the charge was so strong that I could make use of it as a very powerful weapon of defence. After the Arabs had watched our proceedings for a time with wonder, they came to the conclusion that we were engaged in sorcery, and requested us to leave the pyramid. As their remarks, when interpreted to us, were without effect, they wanted to use the power of the strongest to remove us from the top by violence. I withdrew to the highest point, and fully charged my strengthened flask, when the Arab leader caught hold of my hand and tried to drag me away from the position I had attained; at this critical moment I approached the top of my flask to within striking distance of the tip of his nose, which might be about 10 m.m. The action of the discharge exceeded my utmost expectation. The son of the desert, whose nerves had never before received such a shock, fell on the ground as though struck by lightning, rushed away with a loud howl, and vanished with a great spring from our vicinity, followed by the whole of his comrades. We had now a full opportunity of carrying out our experiments."

Before 1860, when Siemens published his paper on a reproducible unit of resistance, there was no generally accepted unit, so that it was impossible to compare the results obtained by any one observer with those obtained by any other. The need of such a unit is very well illustrated in one of the early papers in these volumes, where the unit of resistance used in an investigation is said to be the resistance of an iron telegraph wire 2 m.m. thick and 100 Russian versts long! At the present day, with our well-defined systems of electrical units, it is almost impossible to imagine the difficulty and confusion which must have existed when resistances, to take one example, were stated in such terms as that mentioned above. It is true that Jacobi had previously proposed as unit the resistance of a certain copper wire in his possession, and had issued copies of this unit. These copies, however, varied so much one from another as to be quite useless for the more refined and accurate measurements which the previously mentioned tests for localising the faults in underground conductors rendered necessary. Weber also had proposed his "absolute" unit of resistance, but at this time no trustworthy experiments had been made so as to embody this "absolute" unit in a material resistance. Siemens was thus led to the adoption of another arbitrary unit of resistance, and for this purpose chose the resistance at 0° C. of a column of mercury 100 c.m. long and having a cross section of one square millimetre. He employed mercury, since it can be comparatively easily prepared in a practically pure state, and being a liquid its molecular condition, and hence its resistance, does not alter with time, as it was quite possible that of a solid metallic wire might do. This unit, known as the Siemens unit, came into very general use, particularly on the continent. Nevertheless, the Paris Congress in 1881 decided to use as the international unit of resistance the nearest approach possible to Weber's "absolute" unit, in order to bring the resistance unit into agreement with the other electrical units. On this subject Siemens says:—

"It was certainly somewhat hard for me, that my resistance unit, arrived at with so much trouble and labour, which had, speaking generally, made the first comparable electrical measurements possible, then was employed for more than a decennium throughout the world and adopted as the legal international standard resistance for telegraphy should have suddenly to be set aside with my own co-operation." (Siemens was the German representative at the Paris Congress.) "But the great advantage of a theoretically established system of standards consistently carried out necessitated this sacrifice offered up to science and the public interest."

One cannot help sympathising with him in this matter, for it is always hard to disown one's own offspring, particularly after they have had a comparatively long and brilliant career.

Most of the earlier papers in both volumes deal either directly or indirectly with telegraphy. In the remaining portions of either volume, however, a very prominent part is played by papers and inventions in connection with the conversion of mechanical energy into electrical energy. In connection with a form of magneto-electric machine, *i.e.* one in which the magnetic field is produced by permanent steel magnets, for use in telegraphy, Siemens invented a form of armature, which has since been known as the Siemens armature. This armature is shuttle-shaped and has an iron core, the cross

section being something like an H, and has the wire wound longitudinally in the two grooves. Wilde, who may be said to have taken the first step in the direction of the evolution of the modern dynamo, combined two machines with Siemens' armatures, one a small magneto, the other a large machine with electro-magnets in place of the permanent steel magnets. The armatures of these two machines were rotated, and the current from the magneto was led round the electro-magnets of the other machine. In this way, the magnetic field in which the armature of the large machine rotated, was very much stronger than it was possible to obtain with permanent magnets.

"The technical knowledge of the production of electric currents by means of mechanical power had extended thus far," says Siemens, "when I succeeded, in the autumn of 1866, in obviating entirely the need of steel magnets. The well-known fact that the electric current driving an electro-magnetic machine (motor) is considerably weakened by the induced currents produced in the windings of the electro-magnets, made it appear probable to me that by driving a properly constructed electro-magnetic machine backwards, the slight magnetism remaining in the electro-magnets must be considerably increased since the induced currents are then produced in the same direction as those due to the existing magnetism. Experience confirmed my conjecture. I called this new kind of current-producing machine dynamo-electric, as by it mechanical force is directly changed into electric currents, whilst the magnetism only appears as an intermediate product, not as the real source of the current produced."

Siemens communicated a paper on this new dynamo-electric machine to the Royal Academy of Sciences of Berlin, on January 17, 1867. A few weeks later, William Siemens, at his brother's suggestion, communicated a paper to the Royal Society on this subject. This paper was read at a meeting at which Prof. Wheatstone, who, without knowing of Werner Siemens' discovery, had been working at this question, read a paper embodying the same idea. Some time afterwards it became generally known that a provisional patent, which had been kept secret, and which also covered this invention, had been issued to the Brothers Varley in December 1866.

It appears, therefore, that several people hit upon what may be called the dynamo principle almost simultaneously. From the fact, however, that Siemens was the first to publish the discovery, according to the usually accepted principle introduced by Arago, there seems no doubt that his claim for priority is justified.

This claim for priority with reference to the invention of the dynamo is made again and again in several addresses, &c., in the second volume. As most of these papers are mere repetitions, one of another, it is very doubtful whether any good purpose is served by printing more than one, since the reader becomes very tired of being taken over the same ground several times.

At the end of the second volume there are a number of patent claims, &c., for meters to measure electrical energy. The demand for such a meter, which should combine accuracy with a moderate cost, arose directly the supply of electric current for lighting and power purposes became at all general. Such a demand in connection with any electrical subject was always for Werner Siemens almost a mandate, and he at once devoted a good deal of time and attention to supplying this want.

The chief interest of most of the papers is, no doubt, historic; the two last of all, however, have a special interest at the present moment in this country. They form an appendix to the second volume, and have reference to the foundation by Werner von Siemens of the Physico-Technical Institution at Charlottenburg. The reasons given by Siemens for the foundation of such an institution in Germany apply to the case of our own country at the present day, for we are still without such an institution, though, through the munificence of Dr. Ludwig Mond, the region of usefulness of the Royal Institution is to be extended in this direction. Siemens, during his long and successful career, had noticed that although the general standard of scientific education was probably higher in Germany than in any other country, the result was to produce not so much scientific workers and discoverers as teachers.

"Scientific investigation," he says, "itself is nowhere a life vocation in the State organisation, it is only a permitted private business of the learned besides their vocation, teaching business. . . . It must, however, be pointed out as a waste of national strength, that highly gifted inquirers, talents such as only seldom come to light, are heavily burdened with professional (? professorial) labours, which others would perhaps perform even better, and are thereby in great measure withdrawn from science itself, to which they would bear incalculable service if they could give themselves up entirely to it. But it is a still greater pity that so many talented and highly-cultured young students find no opportunity to carry out scientific work. The unfortunate consequence in most cases is that scientific labours which would animate and fructify whole domains of life, remain undone, and that, in the struggle for existence, talents do not develop or fall to the ground unrecognised, which under more favourable circumstances would have been able to perform great things to the honour and to the material advantage of the country. It is to be feared that the advantage . . . of better scientific instruction and of more widely-spread scientific culture, will soon be lost . . . if it is not supported by State organisations. These organisations would have to fulfil a double purpose, to advance scientific inquiry generally and to aid industry by means of the solution of scientific technical problems and questions which are essential to its development. . . . In order to make clear the great importance which such an institution, well supplied and liberally endowed, would have on the development of industry, a short retrospect of the history of this development is quite sufficient. We see this everywhere associated with persons and institutions, where it was possible by specially favourable conditions that scientific researches went hand-in-hand with their technical applications. The scientific light, which in consequence led technical combinations and methods, gave such institutions such a preponderance over others that the cost of experiments was not only covered by the higher commercial results, but also whole branches of industry were radically transformed by them, and new ones of great importance created. . . . This combination is most easily realisable in chemical manufacture. . . . More unfavourable is, however, the position of the trades depending on mechanical bases. Exact physical experiments demand much more costly instruments and specially-prepared rooms. . . . If the State, therefore, confines itself as heretofore only to looking after instruction, the mechanical crafts necessarily lag behind the chemical in their development."

Thus spoke Werner Siemens, a man who, by his long and eventful life, was specially qualified to speak with authority on this subject, and the results which have, during the few years of its existence, already been achieved at Charlottenburg are proving him a true prophet.

In conclusion, we may say that these volumes will be found most interesting, not only on account of the insight they give regarding the development of the electrical industry, but also on account of the interesting personality which pervades the whole. W. Watson.

ATMOSPHERIC PRESSURE OF THE NORTH ATLANTIC OCEAN.

Répartition de la Pression Atmosphérique sur l'Océan Atlantique Septentrional, d'après les Observations de 1870 *a* 1889, *avec la Direction Moyenne du Vent sur les Littoraux.* Par le Capitaine G. Rung. (Copenhagen: 1894.)

THIS Atlas, showing the monthly and annual atmospheric pressure and prevailing winds over the North Atlantic and connected seas, is a fine example of cartography and typography. The monographs for this and the other oceans have generally dealt only with February, May, August, and November; but this work presents us with the results for each of the twelve months, and for the year, on a mean of the twenty years from 1870 to 1889.

The really heavy part of the work carried out by Captain Rung has been the calculation of the monthly means from the nine years' daily weather charts of the Danish and German meteorologists from December 1880 to November 1889, including the similar charts of the Meteorological Council for the year ending August 1883. This has been done for eighty points over the ocean between lat. 10° and 77° 30′ N. and between long. 25° E. and 80° W.

It being desirable that the discussion should cover a longer period than nine years, the twenty years ending with 1889 were adopted, these years being selected with the view of utilising the fifteen years' means (1870–84) for this part of the globe which have been published in Buchan's "*Challenger* Report on Atmospheric Circulation," thus greatly facilitating the inquiry. The means for the subsequent five years were independently worked out, and thereafter combined with Buchan's to make up the twenty years' means. The next step was to bring, by the usual method of differentiation, the nine years means of the ocean stations to approximate means for the twenty years. Table iv. gives the means thus calculated for ninety-two coast or land stations surrounding the ocean, and Table v. for the eighty ocean stations. The mean directions of the wind have been calculated for the stations in Denmark and its colonies; but for all other stations the data have been taken *simpliciter* from the "*Challenger* Report." It might materially have aided the inquiry in the north-western part of the ocean if means for pressure and wind direction had been calculated and given for the Labrador stations at Hoffenthal, Zoar, Nain, Okak, Hebron, and Rama, the observations at which have been published from 1882 to 1889.

The monthly and annual means for the eighty ocean stations, and the charting of the results on the thirteen maps, constitute the novel part of Captain Rung's work, and must be regarded as a substantial addition to our knowledge of the meteorology of the North Atlantic. This remark holds good emphatically as regards the northern half of this ocean, and for the five months from May to September. Thus, for these months, we have now a more accurate knowledge of the distribution of atmospheric pressure and of the prevailing winds north of latitude 60 than could have been obtained from any work previously published on the subject.

But such well-merited praise cannot be extended to the working out of the results for the five winter months from November to March. An examination of the Danish and German daily weather-maps of the Atlantic of the nine years for these months shows that over the whole ocean to the north of a line drawn from St. John's, Newfoundland, to Valentia, observations from a ship at sea is an event of extremely rare occurrence. The consequence is that the monthly means for this important region, from which fresh information is so desirable, have been obtained wholly from the observations made at the land stations of this part of the ocean. Hence the results given in the Atlas cannot be regarded as a contribution to the meteorology of the ocean. In this Atlas, what strikes one at first sight as new fact is the distribution of atmospheric pressure during the winter months from the south-west of Greenland round by Iceland to north of Norway, particularly the three or four distinct areas of pressure a little lower than prevails generally over this region. But a close examination of the daily weather-maps themselves suggests the idea that these three or four low-pressure systems may be no more than the outcome of an interpretation, made in constructing these daily maps, of the amount of pressure over the ocean drawn from the pressure and winds observed at the land stations, the interpretation being made in the complete absence of observations at sea. Thus the observations made at the Greenland stations since 1840 amply show that the winds on its coast are very greatly deflected from their true direction, as that would be determined by the distribution of pressure, by the high ground and valleys near the coast. It is in this connection that a discussion of the Labrador observations would have come in so handy.

Captain Rung has raised a side issue to his report in a discussion of the distribution of atmospheric pressure in the interior of Southern Scandinavia, where the Atlas shows a singular local excess of pressure in the winter months, which excess is also plainly shown by his monthly means of the Norwegian, Swedish, and Danish stations. In looking closely at this matter, it is necessary to leave out of view the means for Dovre, Tonset, and Röros, which approach to, or exceed, 2000 feet above the sea, their positions not being suitable in discussing small sea-level differences of pressure such as are here dealt with. We have calculated afresh the January means for all other stations not exceeding 620 feet in height, for the same twenty years, and obtain a set of figures differing widely from those published in the Atlas, which give no countenance to the idea of a local excess of pressure in winter over this region. To test the matter in another

way, several means for the same stations for ten years each from the observations of the last quarter of a century have been calculated, with the result that none of these series show an excess, the only variation being such as appears in the isobars of this region for December, January, and February in the maps of the "*Challenger* Report." Finally, on comparing the means for the twenty years given in the Atlas with those we have newly calculated, the strange result comes out that to the north of a line drawn from near Hernösand in Sweden, to a point fifty miles to the north of the Skaw, the pressure means of the Atlas are all in excess of the other means from 0·030 inch downwards, whereas to the south of this line, the pressure means of the newly calculated stations are all in excess of those of the Atlas from 0·030 inch downwards. For now many years, this error has appeared in nearly all maps published on the continent showing the distribution of atmospheric pressure over its surface; and it received greater currency by being adopted in 1887 in the *Meteorological Atlas*, forming part of *Berghaus' Physical Atlas*. It is probable that the error would never have appeared, if there had been established in Southern Scandinavia a true high level Meteorological Observatory, that is, an observatory situated on a peak such as we have in the Ben Nevis Observatory and the other high level observatories on the continent.

OUR BOOKSHELF.

Text-book of Anatomy and Physiology for Nurses. Compiled by D. C. Kimber. (London: Macmillan, 1895.)

THIS is a book of 268 pages on anatomy and physiology, written by a member of the nursing profession. The author states that the text is compiled from many well-known books, and that nearly all the illustrations are figures taken from standard works. On first taking up the book, we were surprised at the amount of detailed anatomy it is considered necessary to impart to nurses in the American training schools, and we are told that the scheme of the book has been practically worked out in class-teaching. So far as we can judge, the class-teaching is conducted in a radically wrong way. In the first place, there are no directions for practical work anywhere in the book. Anatomy and physiology cannot be taught to any one without observation; and with women entering so practical and serious a profession as nursing, actual observation and simple experiments could be insisted upon and more easily carried out than with a class of school-girls. If the work is to be considered as a text-book only, it is far too difficult to be put at once into the hands of a nurse; yet the author makes no statement about previous knowledge. The descriptions given of structure and functions must surely be in many cases very difficult, if not impossible, for beginners to understand, for such descriptions often consist of a few sentences slightly modified, apparently taken from full accounts found in well-known books. Such detached sentences alone, although correct enough in themselves, can lead to no proper understanding of the subject. The book is burdened with much detailed anatomy, such as of the bones, muscles, development of blood-vessels, which although possibly of use to nurses, would have better given place to a simple, clear, and connected description of the general structure and functions of the body. The arrangement observed in the book is not good, and some subjects are treated of in a wrong connection. For instance, the disposition and action of the muscles of the eyeball are considered in the chapter on muscles in general, as is also the action of the muscles of respiration, and these descriptions are consequently inadequate. There are instances of anticipation of topics, strange sentences thrown in, which must be unintelligible until matters treated of later have been grasped. In the chapter on the heart, the author describes almost at once the arrangement of the muscular fibres of the chambers, before even a general description of the organ is given, or the words auricle and ventricle defined; in fact, the whole description of the heart should be much clearer, and the account of its action fuller and more accurate. It would be easy enough to point out some loose and erring statements, and one or two misprints; we are told, for instance, that water is produced "when two molecules of oxygen unite with one of hydrogen." It is far the best for nurses to learn the anatomy and physiology they require from anatomists and physiologists, and nursing from nurses. The book, however, contains a full and excellent glossary.

Calcareous Cements: their Nature and Uses. By G. R. Redgrave. (London: C. Griffin and Co., Limited, 1895.)

MANY valuable contributions to the wide literature of cements have appeared from time to time in the engineering and chemical journals devoted to the industries. Several of these are of foreign origin.

The author of this work is to be congratulated on having collected, in a handy volume of 222 pages, all the most interesting and important facts dealing with the history, manufacture, testing, &c., of "Calcareous Cements."

The volume is divided into sixteen chapters and eight appendices. The first three chapters are devoted to a historical review of the subject, and then follow in systematic order chapters dealing with the various stages in the manufacture of Roman and Portland cements.

Chapter viii. contains a short but accurate account of the researches of Fremy, Le Chatelier, and Landrin on the setting of cement. The author has given to the subject of cement-testing its fullest importance; the various methods and appliances for determining the strength of cements are fully described, and the use of Unwin's formula is clearly stated. The last chapter deals with different specifications for cement. In connection with this subject, the author deplores the want of a uniform and generally accepted system of cement-testing in this country; and, in the hope no doubt of stimulating consumers and manufacturers to an agreement, he gives, in Appendix E, a full translation of the German standard tests.

It is not encouraging to find that an industry which originated in England with the work of Aspdin and Smeaton is slowly but surely passing over to the continent. The annual production of cement in Germany equals that in England; but that is not all, *starting with raw materials of an exceedingly unfavourable character*, Germany produces a finer and more reliable cement than that manufactured in England, and at no greater cost. French cement is also, as a rule, superior to the English article.

A figure of Scheibler's, or any other form of calcimeter, in the chapter on chemical analysis, due to Mr. Spackman, would help to make the work more complete in itself; and Schumann's convenient apparatus for determining the specific gravity of cement is not mentioned; the cumbrous Keates' bottle is alone described and figured.

The illustrations, thirty in number, are good, and the book is supplied with a very complete index.

E. A. W.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Origin of the Cultivated Cineraria.

It appears to me that Mr. Bateson very imperfectly appreciates the nature of the problem of which he has hazarded what I venture to think an ill-considered solution.

In my last letter I pointed out briefly the grave objective difficulties which he had to face in substantiating his case. As Mr. Bateson is, by reputation, a serious naturalist, I think it was his duty to take up the challenge which I virtually threw down to him, and deal with the points which I brought under his consideration. This he has not chosen to do, but falls back again upon his "historical evidence" and his dialectic.

Now I must confess that I am myself as much bored as I suppose most people must be with the "modern Cineraria." And I grudge the time demanded for the discussion of a point which I brought forward as a merely incidental illustration. It may, however, be useful in saying all that I intend to say in reply to Mr. Bateson, to make a few general remarks on the whole subject.

It is apparently the fashion nowadays for the younger biologists to undertake the reconstruction of the Darwinian theory. The field is undoubtedly open, and posterity may safely be trusted to appreciate the value of their labours. But I cannot but observe that as between them and the author of the theory, there is this difference. Mr. Darwin, as he has told us, spent the best part of his life in studying patiently and sifting critically a vast mass of observation and fact. Ultimately he permitted himself to draw certain conclusions. The result is that if you take any statement which Mr. Darwin has put forward, you may feel assured that behind it is a formidable body of carefully considered evidence not likely to be upset. With the modern writers on evolution, the position is exactly the opposite. They launch their theories gaily on the world, and on demanding their substratum of facts, one is told that that is a matter for future collection. I myself am old-fashioned enough to think that, of the two methods, that of Mr. Darwin is the sounder, the more scientific, and in the long run the more convincing.

I have pointed out again and again the vast wealth of material for the scientific study of variation which is presented every day to the eyes of any one engaged in horticultural practice. The difficulty is that few persons possess either the scientific capacity, the patience, or the leisure for its profitable utilisation. We want, in fact, for the purpose a second Darwin, or at least a Herbert.

In his "Variation of Animals and Plants under Domestication," Mr. Darwin made a use which was remarkably effective of the observations made by "practical men" in horticultural literature. They served his purpose in establishing, as had never been done before, the amount and character of the variation which was possible under artificial conditions, and therefore, by analogy, under natural. But this class of evidence appears to me unsatisfactory for the investigation of the further problem which is at the moment of supreme interest, the nature and laws of variation itself. I think that Mr. Darwin squeezed out of it all that it would profitably yield. And for this reason: the evidence is not scientific—that is to say, it was never drawn up by persons having in view the requirements of scientific exactitude. Those who gave it have been pressed into court in a cause in which they never contemplated engaging. This has the merit of ensuring that their evidence is unbiassed, but it does not allow of its being pushed further than what it is capable of proving.

The defects of horticultural evidence may be illustrated in a variety of ways. One or two will suffice. In the first place, is the weakness of its nomenclature. Horticulturists are not, for the most part, skilled botanists. When they give a plant name, it is impossible to be sure that it is what a technical botanist would accept. It is as if one were reading the writings of a chemist, and when he mentioned potassium, the doubt occurred as to whether it was not lithium which was intended. I do not mean to imply any censure on the horticulturists: they use names current at the moment which are good enough for practical purposes, though they will not stand a critical test. But in after years no technical botanist would dream of accepting them as unimpeachable.

Again, it has often been found that where remarkable hybrids have been recorded, it has been ascertained later that no cross has in point of fact been effected at all. Yet the original announcement will be quoted, and often has been as an undoubted evidence of the fact.

I arrive, then, at the conviction that if any profitable use is to be made of horticultural experience in the study of variation, the so-called historical evidence will have to be discarded. Every step of the investigation must be made under the actual eye of a competent observer, and nothing taken at second-hand.

I will now return to the Cineraria. The feral form had been long lost to cultivation, but some years ago it was reintroduced to Kew from the Canaries. Mr. Rolfe, a member of my scientific staff, illustrated it in the *Gardeners' Chronicle* in 1888, and pointed out the striking changes which it had exhibited under cultivation. These have subsequently interested me because I have been endeavouring to collect facts as to the rate of variation.

Now Mr. Bateson, solely on what he calls historical evidence, still asserts, and in the face of the difficulties which I have pointed out that such a theory presents, that the modern Cineraria is of hybrid origin. Very well; let us assume that as a provisional hypothesis. How is it to be tested? It is easy to see from an analogous case. The horse and the zebra have been crossed; are we justified in asserting that the last winner of the Derby is of zebra descent? The criteria are two, and I think two only: (1) an uncontested pedigree: (2) palpable marks of parental characters.

Now, with regard to (1), practically in plants it cannot be obtained. We can only fall back upon "historical evidence." I have attempted to show above, in a general way, how little scientific value can ordinarily be attributed to this. One cannot be sure that the asserted parents were what they are stated to be. But my object was not to undermine the weight of what Mr. Bateson has brought forward. I accept it and reject it as wholly irrelevant. As my friend Prof. Rolleston was fond of saying, it would be valueless evidence even to convict a poacher.

The fact that certain shrubby Cinerarias with hoary leaves and one with yellow flowers were crossed (if they really were) early in the century, proves nothing as to the existing Cineraria, any more than the cross between the zebra and the horse does as to the parentage of any existing horse.

These shrubby Cinerarias were, as Mr. Bateson states, propagated by cuttings (they are not too easy to strike); and like many other interesting plants, they disappeared from all but botanic gardens towards the middle of the present century.

As I am quite unable, then, to attach any weight to the so-called historical evidence, because I fail to see that it establishes any filiation between the plants with which it deals, strikingly different as they are, and the plant with which I am dealing, there is nothing left but to try (2), and see what evidence of its parentage the plant itself affords.

Now, it is well known that organisms of hybrid origin preserve, in some degree, their parental characters, and this has even been shown to be true of their histological elements. Modern taxonomic botany has met with considerable success in the analysis of plants of hybrid origin into their constituents. The Floras have in consequence been cleared of a multitude of dubious plants, the real nature of which can now be accounted for. And the validity of the method has been established by the results of a corresponding synthesis. We had, then, no hesitation at Kew in applying the test to the Cineraria. Although it had often been examined before, with the assistance of some members of my staff I made a fresh examination. I took copious specimens of *Cineraria cruenta*, and of an average cultivated form, and carefully compared them point by point. Except in the multiplication of the florets in the heads, especially of the ray-florets, we could distinguish no tangible morphological difference. In fact, having accidentally mixed up leaves belonging to the two parcels, I found myself unable with any certainty to refer them back again. This is pretty conclusive evidence of the actual morphological identity of the vegetative organs of the two plants.

The next thing was to compare the cultivated Cineraria with its reputed shrubby "historical" parents. These present well marked and somewhat peculiar characteristics not readily described in non-technical language. But the cultivated Cineraria does not present the smallest trace of any one of them. As far, then, as the matter admits of investigation at all by any known methods, I regard the conclusion which is generally accepted here as a sound one. At any rate, it rests on a careful

consideration of the objective facts which Mr. Bateson wholly shirks.

I now come to the other point. I put colour change entirely aside for reasons which seem valid to me, and which I may take another opportunity of explaining. Apart from these the cultivated Cineraria exhibits no variation from the feral form which may not be described as dimensional. While the foliage has remained approximately constant, the loose corymbose habit has been contracted into a tight corymb, and the heads of florets have been enormously enlarged. While the feral form stands about five feet high, the cultivated one is about eighteen inches. I am disposed to restrict the term "sporting" to a definite morphological change such as is exhibited in the flowers of the garden Chrysanthemum, and recently in the occurrence of an "ivy-leaved" form of the Chinese Primrose. But except a race of so-called double Cinerarias, which did not take the public fancy, the history of the garden Cineraria does not present, as far as I know, any trace of a real morphological change. If I might venture to use a mathematical analogy, I should say that the form of the Cineraria-function has remained unaltered.

Now the object of these dimensional changes has been to make the plant worked upon handy and convenient for decorative purposes. Those points which were unessential for this purpose have been unconsciously neglected, and their stability has not been affected. But I do not doubt that if it had been otherwise the Cineraria might have been brought by this time to any configuration which the cultivators fancied.

As far as I can make out, the transformation of the Cineraria has taken about sixty years to effect. Mr. Bateson will not complain if I quote a few words from one of his own authorities of about that date:—"One species especially merits cultivation, viz. *C. cruenta*. This may be regarded as the parent of many of those beautiful varieties which are so successfully cultivated by Messrs. Henderson." Now my memory of the cultivated Cineraria goes back some thirty years. I can remember when it was a rather lanky plant, about half the height of the feral form, with a somewhat lax inflorescence and far smaller flower-heads than are now to be seen. The present fashionable Cinerarias, with a very condensed inflorescence and very large flower-heads, only date back some ten or twelve years.

I see, therefore, no reason for abandoning my assertion that the evolution of the modern Cineraria has been slow and gradual, and not *per saltum*, and this is in accord with general horticultural experience. As soon as a new plant is introduced, every one wants to get a form with bigger flowers or floral structures than anybody else. There is only one secure path to this result, and that is by taking advantage of seminal variation and selecting the minutest trace of change in the desired direction. By patiently and continuously repeating the operation, almost any desired result can be obtained. The horticultural gambler may hope to reach it by a "sport," but he will not. *Anthurium scherzerianum* is a good illustration. Introduced in 1862, it was little more than a curiosity: now its enormous and brilliant spathes are a conspicuous object at every flower-show. This has simply been accomplished by progressive selection working on seminal variation.

Mr. Bateson has now the coolness to say that "the hybrid origin of cultivated Cinerarias is of subordinate interest." All I can say is that in that case it is a pity that he wasted three columns of NATURE with a discussion of the subject. I should have thought myself that it was a matter of very considerable importance indeed to be able to form an approximate idea of the amount of change in a given time in an unmixed species, and so obtain some measure of the possible rate of evolution, at least in regard to dimensional characters.

For my part, I think that in the study of evolution we have had enough and to spare of facile theorising. I infinitely prefer the sober method of Prof. Weldon, even if it should run counter to my own prepossessions, to the barren dialectic of Mr. Bateson.

W. T. THISELTON-DYER.

Royal Gardens, Kew, May 13.

Some Bibliographical Discoveries in Terrestrial Magnetism.

I HAVE recently made some interesting discoveries pertaining to the history of Halley's famous chart of the Lines of Equal Magnetic Variation (Declination), to which renewed attention is just now being called by Prof. Hellmann's admirable facsimile reproduction of the earliest geomagnetic charts.[1]

The first reproduction in facsimile of Halley's chart was undertaken by G. B. Airy, and published in "Greenwich Observations" for 1869. Airy was led to do this by reason of the fact that he could find no geomagnetician of his time who had ever seen Halley's chart. After diligent inquiry among academies and libraries at home and abroad, it was found that the British Museum possessed a copy, and, it was believed, the *only* copy extant. Since then, Prof. Hellmann has succeeded in tracing two other copies, one at Hamburg (Stadt Bibliothek) and one at Paris (Bibliothéque Nationale), and has also, since the publication of his book (as he has just informed me), come into possession of a copy himself.

I have personally examined the Hamburg and Paris copies, and, during a brief stay in London in March, also the copy in the British Museum used by Airy. I have found, moreover, in the British Museum, three other Halley charts and two Dutch reprints. By a careful and critical study of these various copies, some new light is thrown upon the publication of Halley's chart. To make this apparent, some wearisome details with regard to the various copies will be necessary. I will begin with the British Museum copies.

Catalogue No. 974 (5).—"A new and correct Sea-chart of the Whole World, showing the Variations of the Compass as they were found in the Year 1700, by Edmund Halley." Date (according to the Catalogue), 1701.

The above is the English title of the chart referred to at times by the Latin title, "Tabula Nautica," &c. This copy appears to be the one used by Airy in his facsimile reproduction of the Halley chart published in "Greenwich Observations" for 1869, which in turn has been used for Prof. Hellmann's reproduction. There is no date on the chart, nor the name of the publishing firm. The date 1701, assigned hitherto, is probably due to Halley's defence of his chart, contained in *Phil. Trans.* vol. xxix. (Unabridged), 1714. Halley says, p. 165, "to examine the chart I published in the year 1701, for shewing at one View the Variations of the Magnetical Compass, in all those Seas with which the English Navigators are acquainted." But we find that the above number is dedicated "To his Royal Highness, Prince George of Denmark, Lord High Admiral of England, Generalissimo of all Her Majestie's Forces." As Prince George, consort of Queen Anne, did not bear this title until April 17, 1702,[2] it is evident that the above number is either not the original Halley chart published in 1701, or it is a reprint with a later dedication. If it is to be regarded as an original Halley chart (not a reprint), then a date between 1702 and 1708 must be given it, as Prince George died October 28, 1708. It was published probably not far from 1702, and is in excellent condition.

No. 973 (15). Same title as previous number. Date given in the Catalogue, 1720(?) I found upon examination that this is identical with No. 974 (5). The Catalogue date is doubtless erroneous. This copy is cut into sections and remounted.

No. S. 112 (6). This is a large folio atlas containing a reprint of No. 974 (5), bearing now the name of the publishing firm, R. Mount and T. Page, and having in addition an extra strip, from 90° to 160° E. of London, pasted on the left-hand side, so that the chart now embraces 430° of longitude instead of 360 as before. The Hamburg and Paris copies are exact duplicates of this, the only difference being that they have pasted below a strip bearing the explanation of the chart by Halley. Prof. Hellmann, in the work cited, has given us the Hamburg text. The Paris text differs in the orthography of a few words, and in the spacing of some of the lines. It appears to be the older text, as below it we find the name of the firm as R. and W. Mount and T. Page, while the name of the firm on the Hamburg text is Thomas Page and William Mount, and the former I have ascertained to have been the earlier firm. This English text I have failed to find attached to the British Museum copies.[3]

[1] Neudrucke von Schriften und Karten Über Meteorologie und Erdmagnetismus. Herausgegeben von Prof. Dr. G. Hellmann, No. 4. . . . E. Halley, W. Whiston, J. C. Wilcke, A. von Humboldt, C. Hansteen: Die ältesten Karten der Isogonen, Isoklinen, Isodynamen; 1701, 1721, 1768, 1804, 1825, 1826. 4to. 26 pp. 7 plates. (Berlin: A. Ascher and Co., 1895.)

[2] Rapin de Thoyras's History of England, London, 1751, vol. iii. 1689-1707, p. 544.

[3] The atlas contains, besides "An Account of the Methods used to describe Lines on Dr. Halley's Chart of the Terraqueous Globe," &c., by W. Mountaine and J. Dodson, London, 1758, and copies of the Halley chart revised for epochs 1744 and 1756. It bears the title on the hack: "Tabulæ Nauticul Variationes Magneticas Denotentes. E. Halley." It appears to be a compilation of charts, probably by the authors (Mountaine and Dodson) of the revision.

Nos. 974 (6) and 974 (1) are Dutch editions by R. and I. Ottens, of Amsterdam, of the Halley chart as modified and found under No. S. 112 (6). The base of the chart has been changed, but not the lines of equal variation. The dedication to Prince George has been omitted. The dates assigned by the Catalogue are respectively 1735 (?) and 1740. The chief interest in these Dutch reprints lies in the fact that they have a French text pasted on the left-hand side, and a Dutch text on the right-hand side, over Halley's name.

No. 974 (4). "A new and correct Chart showing the Variations of the Compass in the Western and Southern Oceans, as observed in ye Year 1700 by his Maties Command by Edm. Halley." Date given by the Catalogue, 1720, marked doubtful. This chart extends from 50° N. to 59° S., and from $21\frac{1}{2}$° E. to 100° W. of London. It is enclosed by a border; the base of the chart is entirely different from that of 974 (5); yet the equal variation lines, as far as given, are identical with those for the same region on 974 (5). In but one respect is there a difference in the lines, viz. in no case are they drawn over the land, and in a few cases, also, they are slightly extended. It contains in addition the course of the *Paramour Pink*, the ship in which Halley made his observations, 1697–1700, with the chief aid of which he drew the equal variation lines for the Atlantic Ocean. But the matter of chief importance is that this chart is dedicated to *King William III.* This fixes its date. William III. died March 8, 1702. It is highly probable, then, that this is the chart published in 1701, referred to by Halley in the above quotation, and, in consequence, *the original Halley chart.* It is, moreover, reasonable to suppose that Halley would dedicate his first chart to King William III., who had furnished the means for the making of the observations, to which the chart was due. This chart has escaped the attention of all geomagneticians and bibliographers, and the British Museum copy may be the only one in existence.[1]

Another matter of historical interest, apparently unknown to all modern authors in terrestrial magnetism, was ascertained. I find it asserted that the Frenchman, L. I. Duperrey, was the first (1836) to construct the "Magnetic Meridians" for the whole earth, *i.e.* those lines on the earth's surface marking out the path described by following the direction pointed out by a compass needle. It seems, however, that this honour should be accorded to an Englishman, Thomas Yeates, who, in 1817, published a chart of the Lines of Equal Magnetic Variation, accompanied by a "New and Accurate Delineation of the Magnetic Meridians." A second edition of this chart was published in 1824. Copies of both editions were found in the British Museum.

Washington, April 20. L. A. BAUER.

The Unit of Heat.

DR. JOLY'S strictures on the units of heat at present in use will meet with a ready endorsement from those who have worked on calorimetry. The large calorie is too large for convenience in most cases, and the small calorie is too small, while the confusion created by different writers using different units with the same name is scarcely reduced by their writing one with a capital and the other with a small c. A unit of convenient magnitude would be one equivalent to about 100 small calories, and 100 calories has, indeed, been adopted as a unit by more than one writer on thermochemistry. There is, however, what may be termed a natural quantity which is nearly equivalent to such a unit, namely, the heat of fusion on one gram of water at 0° C., which is nearly eighty calories. This appears to be just as suitable from other points of view as the heat of vaporisation of one gram of water at constant temperature and 760 m.m. pressure; and if this latter can be recommended on the ground that in defining it we replace the thermometer by the barometer, the former will possess the superior claim of (for all practical purposes) not depending even on the barometer.

If I remember rightly, this unit has already been adopted in one work on thermochemistry.

No doubt the heat of fusion of water requires redetermination; but it should be determinable with quite as much accuracy as the heat of vaporisation.

Neither of these proposed units, however, possess what should be the chief characteristic of a physical unit, namely, a simple relation to other units; and before adopting either of them, it would be well to consider whether some convenient unit related to, say, the electrical units, could not be adopted. A Committee of the British Association would be a body most suited to investigate this matter.

For practical purposes, a quantity which is even of greater importance than the magnitude of the unit adopted, is the relative value of the heat capacity of water at different temperatures. In spite of the large amount of work which has been expended on this subject, great uncertainty still prevails respecting it. The heat capacity of water, and the heat of fusion of ice, are subjects which I have been for some years intending to turn my attention to, and the work is now practically in hand.

Harpenden, May 4. SPENCER PICKERING.

MY objection to the latent heat of water unit is that this is an inaccessible unit on account of the difficulties attending measurements with the Bunsen calorimeter.

Some years ago I began experiments on a gravimetric ice calorimeter. I have not had leisure to go on with them, but the results obtained were very encouraging. The substance was cooled below 0° while hanging suspended from one arm of a chemical balance. This was effected in a double-walled chamber of copper. A tube, stopped by a plug, connected this chamber with a reservoir of water and clear broken ice. The water was previously boiled to expel air. On raising the plug the water at 0° flows rapidly into the calorimeter, and a shell of clear ice forms upon the substance. The effect on the balance is noted, and by observing the change of buoyancy upon the melting of the ice, and knowing the density of ice at 0°, the mass of the latter can be estimated. The weight measurement will extend to about 0·5 of a calorie. In the steam calorimeter the weight measurement extends to 0·1 calorie, or even less.

There is, of course, much to be said for a thermo-dynamic unit. The question is certainly deserving of having the opinions and views of scientific men fully expressed upon it—as Mr. Pickering suggests. A glance at any of the recent accurate thermal work done in England will show what confusion there exists as to what is the calorie, and as to how all the pet calories of various physicists are related. To render many old measurements of value, this last question should be decided. It reminds one of the state of thermometry in De Saussure's time.

Trinity College, Dublin. J. JOLY.

Reputed Traces of Negrito Pygmies in India.

MAY I be permitted to suggest to readers of M. Quatrefages' work on the Pygmies, the English edition of which has recently been reviewed in NATURE, to pause before accepting his conclusions as to traces of Negritos being found in peninsular India.

The evidence he relies on partly consists of a description by M. Rousselet of a half-starved wanderer from Sirjuga, whom he assigns to the race Bander Lokn (or, as it is printed in the English edition, Bandra Lokh) and the tribe Djangal. Any Anglo-Indian with the slightest knowledge of the language, not to say of ethnology, would be amused at such nicknames being applied as definite racial terms. The first simply means monkey-people (equivalent to savage), as applied by dwellers in the plains to the wilder inhabitants generally; and the second, if it can be said to mean anything in the form presented, is simply "jangli," or a dweller in jungle.

The portrait of this "Djangal," from a rapid pen and ink sketch, is a caricature of a somewhat exceptional and by no means typical individual, and affords no trustworthy material for an ethnological discussion.

The "fever-stricken inaccessible" region Sirjuga,[1] from whence this specimen was a fugitive, according to M. Rousselet, is well known to me, and when travelling there I spent some days in the company of the late General Dalton; and not only then, but in connection with the production of his great work on the Ethnology of Bengal, to which I had the privilege of contributing, I had many conversations with him regarding the tribes of that region. I was, moreover, well acquainted with the true Negritos of the Andamans, of whom I had then already seen many; and I do not hesitate to say that I never met with the slightest trace of a Negrito element among the numerous tribes I became acquainted with during many years travelling in the hilly tracts of Western Bengal, the Central Provinces and the Northern Provinces of Madras. Individuals belonging to different tribes

[1] Upon [illegible] Prof. Hellmann with a brief description of this chart, he [illegible] found that Le Monnier, in his [illegible] Lois du Magnétisme, Paris, 1776 and 1778, has reproduced it. Prof. Hellmann's copy of the Halley chart is a [illegible] No. S 112 (6), with the exception that it embraces but [illegible] of longitude. It also has no text.

[1] The district of Sirjuga in Chota Nagpur is not near Amerkantak, nor is it included in the Vindhyan Range, as is stated by M. Quatrefages.

with curly, not really woolly, hair are occasionally to be seen; but I venture to think that such occasional freaks are casual, and wholly without significance; although they were regarded as evidence of a Negroid element in the population by the late Sir George Campbell.

As, in consequence of the statements and theories of M. Quatrefages, the idea is already spreading that traces of pygmy Negrito races are to be found in these parts of India, I contemplate on a suitable occasion, ere long, publishing some notes, made at the time, on the tribes I met with in my travels in the wild regions referred to. I shall therefore say no more at present, save that the evidence culled by M. Quatrefages out of General Dalton's lithographed groups—one of a girl with her hair *cropped* short, and another of two somewhat curly-headed Sonthals—in support of his theory, is not merely feeble, but is liable to mislead.

Sir Wm. Flower has referred to the use by M. Quatrefages of the term Mincopie for the Andamanese. As he points out, there is in reality no such term. How it originated, though long unknown, has been suggested by Mr. Man. Its derivation foiled even the acute research of Sir Henry Yule. Its first use was by Lieut. Colebrooke in the year 1795, but it has not been recognised in any Indian dialect, and does not seem to have ever been in use among Anglo-Indians, any more than is the name Zebu, which is used in some European languages for the humped cattle of India. Such names, and there are a few others, not being current in the country itself, have to be forgotten by those who visit India. I well remember being not understood when I used the term Zebu on my first arrival in Calcutta some thirty years ago. V. BALL.

Dublin, May 13.

Epping Forest: an Explanation.

SOME years ago you were good enough to publish a paper of mine on the conservation of the Forest from the naturalists' point of view (vol. xxvii. p. 447). That paper was written soon after the Forest was taken over by the Corporation of London, when some unpleasant signs of artificial treatment had become manifest, and more especially with reference to certain railway schemes which, in the interest of naturalists, we of the Essex Field Club felt it our duty to oppose. It is a matter of ancient history that our opposition was successful. My object in entering the lists again is to assure your readers, as representing the scientific public, that the controversy which is now going on concerning the management of the Forest has nothing whatever to do with the agitation about the railway scheme of 1883. This statement may appear superfluous, but I am compelled to trespass upon your space because certain unscrupulous critics are in the habit of misleading the public by quoting from that paper published twelve years ago, without giving date or context, and without a single word of explanation as to its object. Moreover, the critics in question have endeavoured, by a method which in other controversial spheres would be called by a very strong name, to make it appear that some of the views put forward in 1883 are opposed to the attitude which, it is well known, I now hold in the present controversies. So far as naturalists are concerned, they may rest assured that nothing that is now being done is in the way of injury to the Forest; far from this, there are signs of marked improvement The policy of the Conservators is to restore the Forest to a natural condition by thinning out overcrowded pollards which are now beginning to injure one another, and to kill off the varied undergrowth which is such a relief to the gloomy barrenness of an unnaturally dense growth of trees. I may point out that the overcrowding is due to two opposite causes, viz. to entire neglect in some parts, and to too much attention in others. The latter cases refer to those parts in which in past times the rights of lopping were severely exercised. Here of course, now that the Conservators have extinguished these rights, the pollards are throwing up straight and lanky branches of a most unsightly character. In those very limited parts which were not formerly pollarded, and which consist of groves of spear trees, no attempt at systematic thinning had been made before the present Conservancy, and here also there is an overcrowding necessitating woodcraft. Within the last few years all that has been done has been done with care, skill, and forethought. I rejoice to be able to bear testimony on this point, and to reassure those who may have been misled from a want of personal knowledge of the nature and history of the district, into giving credence to the intemperate correspondence in the newspapers. R. MELDOLA.

May 21.

PROFESSOR LOTHAR MEYER.

Gestern Abend 11 Uhr entschlief plötzlich sanft und schmerzlos im 65. Lebensjahre mein lieber Mann

DR. LOTHAR MEYER

ord. Professor der Chemie an der Universitat Tübingen.

JOHANNA MEYER geb. Volkmann
mit ihren Kindern.

Tübingen, den 12. April 1895.

WE were thankful his "falling on sleep" was "sudden, gentle, and without pain"; but we grieved he should have left us so soon.

Julius Lothar Meyer was born at Varel in Oldenburg, on August 19, 1830. After completing his school course in the Gymnasium, he studied in the University of Zürich from 1851 to 1853, then at Würzburg from 1853 to 1854; from Würzburg he went to Heidelberg, where he remained till the autumn of 1856, and from thence he migrated to Königsberg, where he remained until Easter 1858. Meyer's original intention was to devote himself to medicine, and he graduated as Doctor in Medicine at Würzburg on February 24, 1854. At Heidelberg he came under the influence of Bunsen, and his work became more and more chemical. At Königsberg his studies were devoted mainly to mathematical physics, under the guidance of F. Neumann. In 1858 he took the degree of Ph.D. at Breslau; and on February 21, 1859, he received leave to teach chemistry and physics. From 1859 to 1866 Meyer was in charge of the chemical laboratory of the Physiological Institute at Breslau. In 1866 he was called to the Royal Prussian *Forstakademie* at Eberswalde, where he remained until 1868, when he went to the *Polytecknikum* at Carlsruhe. In 1876 Prof. Fittig was called from Tübingen to the University of Strassburg, and Lothar Meyer was appointed to fill the vacancy at Tübingen.

He had nearly completed twenty years' work at Tübingen when the summons came. Cerebral apoplexy stopped his labours, on April 11 of this year; and, *plötzlich, sanft, und schmerzlos*, he passed.

It was while teaching chemistry and physics at Breslau that Meyer published the first edition of the work on which his reputation as a philosophical chemist chiefly rests. "Die Modernen Theorien der Chemie" appeared in 1864. A second edition was published in 1872; and since that time have appeared a third, fourth, and fifth edition. At the time of his death Meyer was engaged in the preparation of a sixth edition, which he intended to publish in three, more or less independent, parts. An English translation of the fifth edition, by Messrs. Bedson and Williams, appeared in 1888. In 1883 Profs. Meyer and Seubert recalculated the atomic weights of the elements from the original data, and laid all chemists under a debt of gratitude by publishing their results, under the title "Die Atomgewichte der Elemente aus den Originalzahlen neu berechnet."

Lothar Meyer was one of the earliest investigators of the relations between the properties and the atomic weights of the elements. In the first edition of his "Modernen Theorien" published in 1864 he traced relations between the atomic weights and the chemical values of the elements; and in December 1869 appeared a memoir by him entitled "Die Natur der chemischen Elemente als Funktion ihrer Atomgewichte," wherein he arranged the elements in order of atomic weights, in a single table, and indicated the periodic character of the dependence of properties on atomic weights.

The clear enunciation, and the application in detail, of the most far-reaching generalisation that has been made in chemistry since the work of Dalton, must, undoubtedly, be credited to that great chemist Mendeléeff

but, nevertheless, a perusal of the controversy between Mendeléeff and Meyer shows, I think, that Meyer arrived at the fundamental conception of the periodic law independently of Mendeléeff. Those who are interested in such controversies will find papers by Mendeléeff and Meyer in *Berichte* xiii. pp. 259, 1796, 2043 [1880].

In his discourse to the German Chemical Society on May 29, 1893, "Ueber den Vortrag der unorganischen Chemie nach dem naturlichen Systeme der Elemente," Meyer quotes the words which Laurent had used fifty years before concerning organic chemistry, and applies them to the teaching of inorganic chemistry at the presen time:—*que l'arbitraire y règne sans partage.* If these words can be applied to the teaching of inorganic and general chemistry to-day, how much more fully and literally were they applicable at the time when the first edition of Meyer's "Die Modernen Theorien" appeared thirty years ago! That book has probably done more than any other publication within the twenty years after 1864 to advance the study of comparative chemistry; its influence on the conception of chemistry as an accurate and orderly body of facts and principles has been very great, and has been wholly good. The labour bestowed on the preparation of the first edition of the "Modern Theories" must have been immense. The author speaks in his preface of rewriting the MS. three times. It is true that thirty years ago physical chemistry was practically non-existent, that the facts of organic chemistry could be mastered and held by a man with an ordinary memory, and that one might be a chemist without first being a mathematical physicist. But it is also true that the facts of inorganic chemistry had not been coordinated by the luminous conception of the periodic law, that there was a lack of clearness in the notions of most chemists about the structure of organic compounds—for Kekulé had not yet made his famous ride on the top of the Clapham omnibus—and that the many isolated facts regarding the influence of temperature, time, and the masses of the reacting bodies, on chemical changes had not been gathered together and illuminated by the law of mass action and the conceptions arising from the applications of this law. It was then that "Die Modernen Theorien" appeared; and at once a flood of light was thrown on the whole domain of chemical science. Old problems were made clear, and new problems were suggested. Chemistry entered on its modern phase.

As the study of comparative chemistry progressed—a study which was introduced by the enunciation of the periodic law—it became necessary to know with accuracy the analytical bases whereon rested the values accepted for the atomic weights of the elements. Hence Lothar Meyer was induced to devote a large amount of labour to the somewhat thankless task of recalculating these values; the result of this work, carried out with the help of his colleague Prof. Seubert, appeared in 1883. This work received additional value from the fact that it appeared almost at the same time as Clarke's "Recalculation of the Atomic Weights." Every worker in this department has the data of all previous workers brought to his hand, and presented in the most manageable form.

Besides these two treatises bearing on general chemistry, Lothar Meyer was an investigator in the sphere of experimental chemistry. He has published memoirs on subjects in almost every branch of the science, on the atomic weight of beryllium, on determinations of vapour densities, on the combustion of carbon monoxide, on the preparation of hydriodic acid, on the transpiration of gases, on various organic compounds, and on other matters.

A great chemist has passed away from us; his work remains, and that work will ever be held in remembrance.

M. M. PATTISON MUIR.

NOTES.

THE Institute of France has decided to solicit subscriptio for the erection of a statue to Lavoisier at Paris. It is intende to make the appeal an international one, so that all admirers of Lavoisier may do honour to the memory of one of the creators of modern science. Subscriptions may be sent to the Treasurer of the Committee for the Lavoisier Memorial, 55 quai des Grands-Augustins, Paris.

THE centenary of the Institute of France is to be celebrated next October. The *Times* states that on the 24th of that month the foreign representatives invited to the celebration will be received, and the Minister of Education will hold a reception. On the following day M. Faure will attend a ceremony at the Sorbonne, and a banquet will be held. There will also be a dramatic entertainment and a reception at the Elysée. Chantilly, the future property of the Institute, will be visited on the 27th, by permission of the Duc d'Aumale.

LIVERPOOL, determined that the visit of the British Association in 1896 shall be a success, has taken time by the forelock. At an influential meeting held in the Town Hall last week, it was announced that an executive working committee had been appointed thoroughly representative of the inhabitants of Liverpool and the neighbourhood. The Chairman is the Right Hon. the Lord Mayor of Liverpool, the Vice-Chairmen are Sir W. B. Forwood and Mr. E. K. Muspratt; the Hon. Treasurer, Reginald Bushell, and the Hon. Secretaries, Prof. W. A. Herdman, F.R.S., Mr. J. C. Thompson, and Mr. W. E. Willink. The meeting was very enthusiastic, and the keynote running through the various speeches was to the effect that the welcome extended to the members of the British Association should not in any direction be allowed to compare unfavourably with that at the meeting at Manchester in 1887, which in the matter of subscriptions at present holds the record. From the short statement made by the Hon. Treasurer, this hope seems likely to be realised. Without making any public appeal for funds, but simply putting the matter before a few of his more influential friends, the Hon. Treasurer was able to make the gratifying statement that no less than £1350 had been subscribed. The Committee preferred a subscription list to a guarantee fund, and in this they are no doubt well advised. A donor, however, is not entitled to any privileges as a member of the British Association, by reason of his subscription, but to every subscriber of £10 a member's ticket or two associate tickets will be given, and one associate ticket to subscribers of £5. With this early start, Liverpool ought to have no difficulty in raising the £5000 which Sir W. Forwood regards as the minimum sum required for a successful and record meeting.

THIS year's conversazione of the Society of Arts will be held in the South Kensington Museum on Wednesday evening, June 19.

DR. THORNE THORNE, C.B., F.R.S., has been appointed a member of the General Medical Council for five years, in place of Sir John Simon, resigned.

MR. GEORGE MURRAY has been appointed Keeper of Botany in the British Museum, in succession to Mr. Carruthers, who retires on superannuation.

THE death is announced of Dr. H. F. C. Cleghorn, well known for his work in connection with the organisation and development of the Forest Department of India. He was for some years president of the Royal Scottish Arboricultural Society, and examiner in forestry to the Highland Society. He also took a leading part in the founding of the forestry lectureship in the University of Edinburgh.

The munificent gift made by Mr. Seth Low, ex-Mayor of Brooklyn, and now President of Columbia College, to that college, at a meeting of the trustees a few days ago, places him in the front rank of the world's benefactors. One million dollars for a library building, twelve scholarships for Columbia College for Brooklyn boys, and twelve to Barnard College for Brooklyn girls, eight university scholarships and a university fellowship, make a list of gifts rarely equalled. At the same meeting, Mr. C. Schermerhorn presented 300,000 dollars for a new building. Then the Townsend library, a complete compilation of all the printed matter relating to the American Civil War, in eighty-nine volumes of 600 pages each, larger than an ordinary ledger, which was begun six months before the war, and is the result of thirty-three years of unceasing labour by Thomas S. Townsend, was formally presented to the college, together with an encyclopædia of reference to it, and 4000 dollars to complete the encyclopædia.

The trustees at the same meeting, following the recommendation made by the National Academy of Sciences at their recent meeting, awarded the Barnard medal to Lord Rayleigh for the discovery of argon. This gold medal, which has a value of 200 dollars, is awarded every five years to the investigator who makes within the preceding five years the most valuable discovery in physics or astronomy, in accordance with the will of President F. A. P. Barnard, who died in 1889, and was the immediate predecessor of Mr. Seth Low.

The Brooklyn Institute has just sustained a great loss in the retirement of General John B. Woodward, who has been president for eighteen years, covering the entire epoch of the great development and expansion of the Institute. He will be succeeded by Mr. A. Augustus Healy.

Sir William Dawson has sent us a printed statement, in which he traverses the arguments against the organic nature of *Eozoon Canadense*, brought forward by Dr. J. W. Gregory and Prof. Johnston-Lavis, in a recent paper entitled "Eozoonal Structure of the Ejected Blocks of Monte Somma," noted in our issue of January 10 (p. 251). He states a number of facts which indicate "that the specimens of Eozoon found in the Laurentian limestone of Canada in no respect resemble in their associations and mode of occurrence the banded forms from Mount Somma described in the paper in question."

A strong earthquake disturbance of about five seconds' duration occurred at Florence at nine o'clock on the evening of Saturday last, and was felt at Bologna four minutes earlier. Two hours later another shock was felt. Many of the houses in Florence were injured by the movements, but the damage appears to have been greater in the surrounding villages—Grassina, Lapaggi, and San Martino, where the church was destroyed. At Orezzo the earthquake is said to have lasted ten seconds, and there were two distinct shocks at Siena. The movement was strongly marked at Parma, and to a less degree at Pisa and Placentia. Reuter's correspondent at Spoleto reports that severe shocks were also felt there on Monday evening.

A general meeting of the Federated Institution of Mining Engineers will be held in London on Thursday, May 30, and on Friday, May 31. The presidential address will be given by Mr. W. N. Atkinson on the Thursday. The papers to be read on the same day are:—Notes on bauxite in County Antrim, &c., and its uses, by Mr. George G. Blackwell; sampling, by Mr. T. Clarkson; blasting explosives, by Prof. Vivian B. Lewes; and the gold-milling process at Pestarena, by Mr. A. G. Charleton. At the meeting on May 31 the following papers will be read, or taken as read:—Remarks on the banket formation of Johannesburg, Transvaal, by Mr. A. R. Sawyer; the composition of the extinctive atmospheres produced by various flames and by respiration, by Prof. Frank Clowes; the composition of the limiting explosive mixtures of various gases with air, by Prof. Frank Clowes; the mineral oils of Lower Elsass, by Dr. L. van Werveke; copper-mining in India, by Mr. Robert Oates; the recent magnetic survey of the United Kingdom, by Prof. A. W. Rücker; the MacArthur-Forrest process, by Mr. John McConnell.

In consequence of the renewed attacks upon the Conservators of Epping Forest, another large and influential meeting of the Essex Field Club was held on Saturday last, under the conductorship of Mr. Edward North Buxton, Prof. Boulger, Prof. Meldola, and the hon. secretaries. More than 100 members and visitors were present, among them being many residents in the district and lovers of the Forest, as well as such well-known experts as Prof. W. R. Fisher, of Cooper's Hill, and Mr. Angus D. Webster. The districts visited were those about which complaints had been made by a certain class of newspaper correspondents, viz. Bury Wood, the so-called Clay Ride, and Monk Wood. Beyond a few personal discussions between the conductors and experts and one or two of those who had been criticising the action of the Conservators, no public ventilation of views was permitted, as the conductors were of opinion that a mere inspection of the places named would enable the members and their friends to form their own conclusions. The party assembled at the King's Oak at High Beach for tea, after which an ordinary meeting of the Club was held, the President, Mr. David Howard, taking the chair. Mr. E. N. Buxton explained a scheme which he had been carrying out for the purpose of affording protection to the birds of the Forest district. By enlisting the sympathies and securing the co-operation of the surrounding landowners, he had succeeded in obtaining a promise that a total area of some 20,000 acres, including the 6000 acres of Forest, should constitute a sanctuary within which no rare or interesting birds should be destroyed. The President indicated that such an organisation as the Essex Field Club was well calculated to enforce by example and precept the desirability of protecting both animals and plants. Mr. F. C. Gould, in reply to those correspondents who had stated that the birds were becoming rarer in Epping Forest, said that this was quite contrary to the facts. Birds were never so plentiful in the Forest as they had been during the past few years, and Mr. Gould gave a list of species which had been observed by his son in the course of one day. After tea the party proceeded to the more northern part of the Forest, and inspected Epping Thicks. Although no formal division on the question of the management of the Forest was taken, the majority could not help expressing their admiration at the skill and judgment with which this year's thinnings had been effected. Many of those present also expressed some anxiety that the Conservators might be influenced by the newspaper correspondence, and allow the Forest to degenerate by acceding to the request recently made by a deputation to the Committee that no further thinning should be allowed for a period of five years.

A spell of very cold weather for the time of year was experienced last week over the entire area of the British Isles, owing to a depression which, at the time of our last issue, lay over Denmark, and caused strong gales from north and north-west over the North Sea. The temperature fell about 30° over the inland parts of England, while snow and hail were reported from many places. On several nights the sheltered thermometer fell to within a few degrees of the freezing-point, and actually reached it in the east and west of Scotland, on the morning of the 17th instant; while the highest day readings have in many parts failed to reach 50°, a temperature which is fully 10° below the average. During the first part of the present week a depression which had spread westwards from Germany, caused a continuation of cold, gloomy weather over our islands.

Some years ago the desirability of publishing the observations made by the late J. Allan Broun at Trevandrum, in Southern India, for over twelve years, was brought before the Royal Society of London by the Royal Society of Edinburgh, and the records were deposited at the Meteorological Office for safe keeping. The Meteorological Council subsequently drew the attention of the Royal Society to the subject, and that body induced the Indian authorities to render this valuable material accessible to scientific men, the result being that the Meteorological Department of India has just published the barometrical and thermometrical observations in vol. vii. of their *Memoirs*. The publication contains the hourly observations and means from January 1853 to December 1864, with the exception of Sundays, on which no observations were taken. The whole of the original entries have been carefully examined for clerical errors, under the superintendence of Mr. J. Eliot, the Government Meteorological Reporter, and we gather from the preface that a discussion of the results will eventually be carried out.

A most eloquent appeal for the wider diffusion of a knowledge of sanitary matters has been recently made by Dr. Carlo Ruata, Professor at the University of Perugia, in his introductory address to a course of lectures on the duties of sanitation. Efficient sanitation, urges Dr. Ruata, may justly be demanded as a right by the individual from the State; but, at the same time, each individual must be adequately impressed with his duties and responsibilities to other members of society in the proper conduct of sanitary matters. It is pointed out how much may be, and has been, done by judicious legislation and enlightened public opinion in recent years; but Dr. Ruata would insist upon more vigorous measures, and upon a knowledge of the principles of hygiene being rendered compulsory in systems of education. Ignorance and lack of all sense of responsibility is only too frequently to blame for the generation and spread of disease, and Dr. Ruata's appeal, that proper hygienic conduct should be insisted upon as the serious duty which one member of society owes to another is fully justified. Dr. Ruata is confident that with improved hygienic conditions society will benefit not only physically but morally; but whether it will bring about the utopian state sketched by the lecturer in his sanguine peroration, remains yet to be seen.

A report, by Mr. P. G. Craigie, on the agricultural experiment stations and agricultural colleges in the United States, just published as a Parliamentary Paper, should be seen by every one interested in agricultural education and research. It appears that, at the present day, upwards of three-score collegiate institutions are engaged in the United States wholly or partly in agricultural teaching, and, according to the statistics collected and published for 1892, they enjoy an aggregate revenue of £689,000, practically one half of which was granted by the Federal Government, while £223,000 is added by the several States, minor aid being rendered by £40,000 which came from fees, and by the benevolence of local committees or private individuals, while the remainder was raised by the sale of farm produce or miscellaneous receipts. The number of separate experiment stations is fifty-four, of which forty-eight receive subventions from the Federal Government out of national funds, the uniform grant being roughly £3000 to each station. According to the returns published of the revenue of these stations in 1892, upwards of a million dollars, or roughly £200,000, is available as annual revenue, the Federal Government finding £140,000, and the grants of the States reaching rather more than £30,000.

Mr. Craigie's report bears out his conclusion that "great and practical energy is being directed to the discovery of the best means of extending the field of agricultural and horticultural knowledge. It should not be overlooked that side by side with the growth of local stations a very extensive development of the scientific staff engaged on the special inquiries of the Federal Department at Washington has taken place in the last ten years. The American Government seems willing to face any cost to the community that promises the better to equip the farmer with a knowledge of his business. The authorities seem assured that in indicating methods of profitable production, and still more by the careful perfecting of the produce of the vast lands of the Republic, in whatever directions of extensive or of intensive culture the economic circumstances of the moment may prescribe, they are providing a solid means of advancing the well-being of the nation as a whole."

A fresh addition to periodical literature is the *Journal of the South-Eastern Agricultural College*, Wye, Kent, which is to be published three times a year, and is intended to be a brief record of the history of the college from term to term, and to announce the results of investigations and experiments conducted by the college or members of its staff, together with other observations that may seem of interest to the agriculture of the counties of Kent and Surrey. The first number contains a description, with a plan, of the farm attached to the college, together with an account of the dairy school, of the water supply of the college, and of the field experiments which are being instituted. Mr. F. V. Theobald's notes on poultry parasites would appear to open out an instructive field of inquiry. Mr. J. Percival gives an abstract of a paper, already published, relating to eelworms in hop plants, their ravages resulting in the condition of the plants known as "nettle-headed." The nematode *Heterodera Schachtii* attacks so many kinds of plants, that its presence in hops was quite to be looked for. No reference seems to be made to the value which hop-growers set upon rape as a "trap-plant" for enticing the eelworms away from the infested crop. If future numbers are as attractive as this one, the publication is likely to prove acceptable to those in whose interest it is issued.

In a recent number of the *Bulletin Geol. Soc. America*, Messrs. G. K. Gilbert and F. P. Gulliver give an interesting account of the remarkable "tepee buttes" that occur abundantly in the neighbourhood of Pueblo, Colorado. Using the term "butte" to denote steep-sided hills with narrow summits, which may be of very various origin, the authors mention the various types of buttes (volcanic necks, geyser deposits, &c.), and discuss this particular form. They are low hills, less than twenty feet in height, that owe their origin to the resistance to denudation of peculiar vertical masses of limestone occurring in the shales of the Pierre series (Upper Cretaceous). The limestone is composed of shells, chiefly of *Lucina* and *Inoceramus*, united by a matrix of shell-fragments, foraminifera and clay. This structure of the limestone, in comparison with that of the calcareous concretions that occur normally throughout the shale, negatives its concretionary origin, nor does it resemble the spring-deposited masses of limestone known elsewhere. It is concluded that particular local conditions determined the establishment of colonies of Mollusca that continued for generations at these spots, though what these conditions may have been it is not easy to explain. Attention is called to the description, by Dr. Bell, of similar limestone masses in Devonian shales in Canada.

The motion of a pianoforte wire when struck has been investigated by Herr W. Kaufmann, whose paper on the subject in *Wiedemann's Annalen* is accompanied by a set of very interesting photographic records, obtained by a modification of the method invented by Kaps and Krigar-Menzel. By vibrating the wire in front of a luminous slit, and throwing the image of it upon sensitive paper rotating upon a cylinder, a white line is traced upon a black ground. This line, which is due to the interruption of the luminous slit by the opaque wire, exhibits all the motions of the particular point in the wire which is crossed by the slit. In

order to bring the plane of the slit into exact coincidence with the wire, an image of the slit, produced by a lens with the aid of the electric arc, was thrown upon the wire itself. Since the hammer struck the wire at the point photographed, the motion of the wire was traced from the very first, the commencement of the vibration being the most interesting stage. Hard and soft hammers were tried, the latter corresponding to those actually used in the piano. It was found that the duration of contact is longer with feeble than with hard striking. As the force increases, the duration of contact rapidly approaches a limiting value equal to that of a hard hammer of equal weight. But the practically most important resultant was the proof that when a wire is struck at a point between one-seventh and one-ninth of its length, the fundamental tone has a maximum, and the harmonics—especially the third—are very feeble. Hence a wire thus struck gives its strongest and richest tone. This fact is acted upon by piano-builders, but is not explained by supposing that the nodes of the higher harmonics are struck, thus preventing their being heard. They are heard, but are outweighed by the more harmonious ones.

AN interesting paper on the magnetisation of iron in very weak fields, by W. Schmidt, appears in the current number of *Wiedemann's Annalen*. The author uses the magnetometer method slightly modified, a compensating coil being placed on the opposite side of the magnetometer to the magnetising coil. The effect of the iron under investigation on the magnetometer needle is compensated by passing a known current through an independent coil of large radius, so that the method is a "zero" one. A Duprez-d'Arsonval galvanometer was used to measure the current, its constant being determined by means of standard Clark cells. The samples of iron and steel under investigation had the form of ellipsoids, the semi-minor axis being 3 m.m. and the semi-major axis 200 m.m. for one set of experiments, and 150 m.m. for the other. The curves obtained for iron and steel show that for fields up to 0·06 C.G.S. units the susceptibility is constant, thus confirming Lord Rayleigh's results. As the magnetising field increases between 0·06 and 0·4 units, the curve giving the relation between the magnetising force and the susceptibility is a straight line. The author sums up the results of his experiments as follows:—Steel follows weak magnetising forces more quickly than iron. The susceptibility of soft steel is for small magnetising forces greater than that of iron. Thus for fields less than 0·06 C.G.S. unit the susceptibility of soft steel is to that of iron in the ratio of 4 to 3. For magnetising fields of about 1 unit the susceptibility of the two is about the same, while for greater field strengths the susceptibility of iron is greater than that of steel. The limits within which the susceptibility remains constant vary considerably for different samples, but the author considers that 0·06 C.G.S. unit may be taken as the upper limit with sufficient accuracy for most purposes.

THE May number of the *Irish Naturalist* well sustains the reputation for utility and general interest which has been obtained by this periodical. Mr. R. M. Barrington gives an interesting sketch of the career and writings of the late Mr. A. G. More, a naturalist of unusual versatility, who has contributed greatly to our knowledge of Irish Natural History. Mr. Robert Warren writes on the Breeding Birds of Loughs Conn, Carra, and Mask. Dr. R. Hanitsch gives a brief but valuable account of the Fresh-water Sponges of Ireland. The distribution of these forms presents certain features of peculiar interest. The eastern part of the island possesses only common European forms, whereas three out of the four species found along the west coast prove to be American. It is pointed out that the formation of gemmules gives to the Spongillidæ more favourable chances of dispersal than are enjoyed by most other animals. Mr. Clement Reid has examined a sample of marl from which skeletons of the Irish elk had been obtained, and finds that it consists largely of *Chara* and *Potamogeton*. He offers an ingenious suggestion to explain the occurrence of skeletons of *Cervu megoceros* in deposits of *Chara*-marl. Those familiar with pools containing *Chara* will be well aware of the appearance of shallowness, and of a solid floor, which is so deceptive. The plants grow to a depth of several feet, but appear to form a carpet of turf just below the surface of the pools; any animal treading on this turf would immediately plunge head-foremost into the water, and in the case of the elk the antlers would almost inevitably become entangled among the stems of *Chara* and other still tougher pondweeds. This entanglement theory accounts very well for the fact that the remains of stags are far more abundant than those of hinds.

A PHOTOGRAPH of the late Prof. J. D. Dana, taken about six weeks before his death, is reproduced in the current number of the *American Journal of Science*, together with a full biographical notice, and a list of his works.

THE "Year-Book of Scientific and Learned Societies" in Great Britain and Ireland, the twelfth annual issue of which has just been published by Messrs. C. Griffin and Co., is undoubtedly a very useful handbook of reference. A general idea of the progress of science during the past year can be obtained from the lists of papers subjoined to the designations of the various societies.

IN the Michigan Mining School theoretical knowledge seems to be well combined with practical training. We notice in the Calendar, just received, that the elements of astronomy is one of the subjects in which all students are examined for entrance into the School. The course of instruction is arranged so that a good foundation is given in the principles of science, and experience and practice are obtained in every subject taught.

THE new editions received during the past week include the first volume of the British Museum "Catalogue of Fishes," containing the Centrarchidæ, Percidæ, and Serranidæ (part), by Mr. G. A. Boulenger, F.R.S. When the first edition of the work was published, in 1859, the Museum collection of fishes comprised 29,275 specimens. The additions since that date have brought the collection up to twice its dimensions at the time when the original catalogue was compiled. The need for revision will, therefore, be fully understood. In the volume which begins the publication of the new edition of the catalogue, Mr. Boulenger confers a benefit upon ichthyologists by omitting seventy-six imperfectly or incorrectly characterised species. The result of this is that, though many new species are included, the present volume contains only fifty-eight more recognised species than the original one. Mr. Boulenger's list gives 375 species, of which 261 are now represented in the British Museum collection, by 2353 specimens.

NEW editions of two technical manuals have reached us from Messrs. Whittaker and Co. One of these is "Electricity in our Houses and Workshops," an admirable handbook by Mr. S. F. Walker, in which the every-day working of common forms of electrical apparatus is simply described. "The Practical Telephone Handbook," by Mr. Joseph Poole, which is now issued in an enlarged form, should prove of increased value to all interested in the methods of telephone working. A new and enlarged edition (the fourth) of Balfour Stewart's "Lessons in Elementary Physics" has been published by Messrs. Macmillan and Co. In this volume we have a treatise in which the whole domain of physics is covered, and which is so arranged that the connections between the various branches of the subject are clearly brought before the student. Though a quarter of a century old,

if the book is brought into line with modern physics from time to time, it will command success for many years to come. "Wild Nature won by Kindness" (Fisher Unwin), has attained the eminence of a sixth edition. Mrs. Brightwen's pleasantly written papers on natural history subjects are evidently appreciated by a large public. Three books by Prof. S. Cooke, of the College of Science, Poona, published by Messrs. George Bell and Sons, have also been received. They are "First Principles of Astronomy" (fifth edition), "First Principles of Chemistry" (sixth edition), and "Test Tables for Qualitative Analysis" (third edition.)

THE synthesis of caffeine is the subject of a short communication to the Berlin Academy by Emil Fischer and Lorenz Ach (*Sitzb. König. Preuss. Akad. Wiss. Berlin*, xiv. p. 261). By the condensation of dimethyl urea and malonic acid the substance $CO:(NMe.CO)_2:CH_2$, is obtained. The nitroso-derivative, $CO:(NMe.CO)_2:CH.NO$, is reduced to dimethyluramil, $CO:(NMe.CO)_2:CH.NH_2$, whence dimethylpseudouric acid, $CO:(NMe.CO)_2:CH.NH.CO.NH_2$, is produced. By abstraction of the elements of water with oxalic acid, dimethyluric acid is formed. This substance is converted into theophylline, an isomeride of theobromine, of the formula

$$CO\begin{array}{l}\diagup NMe.CH:C.NH\diagdown \\ \diagdown NMe\ .\ C:N\diagup\end{array}CO.$$

Thence caffeine,

$$CO\begin{array}{l}\diagup NMe.CH:C.NMe\diagdown \\ \diagdown NMe\ .\ C:N\diagup\end{array}CO,$$

is obtained by the ordinary methyl iodide reaction. As this is the first synthesis of caffeine, details of the methods used will be looked forward to with considerable interest.

THE observation by Martin Freund and Ernst Göbel, that thebaine is a derivative of phenanthrene (*Ber.* 28, 7, 941) brings this alkaloid into line with morphine and codeine as instances of the few natural phenanthrene derivatives yet known. Thebaine is related to dihydrophenanthrene in the same manner as morphine and codeine are connected with tetrahydrophenanthrene.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*, ♀) from Natal, presented by Mr. Alfred James; a Common Jackal (*Canis aureus*), two Bengal Foxes (*Canis bengalensis*), a Jungle Cat (*Felis chaus*) from India, presented by Dr. John Anderson, F.R.S.; two Short-tailed Capromys (*Capromys brachyurus*) from Jamaica, presented by Mr. Frank Cundall; a Dorsal Squirrel (*Sciurus hypopyrrhus*) from Central America, presented by Mrs. Brett; five Squirrel-like Phalangers (*Belideus sciureus*) from Australia, presented by the Right Hon. Earl Cadogan, K.G., a Cambayan Turtle Dove (*Turtur senegalensis*) from West Africa, presented by Mr. C. L. Sutherland; a Salle's Amazon (*Chrysotis sallæi*) from St. Domingo, presented by Mr. W. Windsor Spriggs; a Spotted Salamander (*Salamandra maculosa*), European, presented by Mr. E. Layton Bennett; two Great Wallaroos (*Macropus robustus*, ♂ ♀), two Agile Wallabies (*Halmaturus agilis*) from Australia, a Blue and Yellow Macaw (*Ara ararauna*) from South America, deposited; two Canada Geese (*Bernicla canadensis*) from North America, two Yellowish Weaver Birds (*Sitagra luteola*) from Tropical Regions, thirteen Green Lizards (*Lacerta viridis*) from Jersey, purchased; a Malaccan Parrakeet (*Palæornis malaccensis*) from Malacca, a Nicobar Pigeon (*Calænas nicobarica*) from the Indian Archipelago, received in exchange; a Bennett's Wallaby (*Halmaturus bennetti*, ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

STARS WITH REMARKABLE SPECTRA.—At those stages of celestial evolution in which the temperature is low, it is probable that the average condensing body will not be very bright, so that the study of their spectra at these phases of their development presents some difficulties. Thus, the great majority of the stars with bright-line spectra, and stars showing intense carbon absorption, are of low magnitudes, and because comparatively few were identified in the earlier surveys of stellar spectra, they were looked upon as "peculiar." Nevertheless, a study of these spectra in relation to those of the brighter stars indicated that they probably represented stages in the history of all condensing bodies, so that their discovery in greater numbers was only to be expected. At Harvard College especially has the photographic investigation of these faint spectra been carried on, and the discovery of eleven more objects with peculiar spectra has been recently announced by Mrs. Fleming; two of these are simply stated to be "peculiar," three are nebulæ with bright lines, two have the F line of hydrogen bright, two appear to be bright-line stars of the Wolf-Rayet type, and two show carbon absorption. In addition, the spectra of eleven stars of the α Herculis type were found to show the F line of hydrogen bright, and this unfailing sign of variability in this group of stars is fully substantiated by an examination of chart plates of the same regions. (*Astrophysical Journal*, May.) In his observations of the visual spectra of faint stars, Rev. T. E. Espin has discovered numerous objects which he describes as "remarkable." (*Ast. Nach.* 3286.) Most of these, however, appear to be of the α Herculis type; but some are spectra in which carbon absorption is predominant (Group VI.). The most interesting observations by Mr. Espin are those of variable stars, and they tend to show that, in the stars of Group VI., the variability is accompanied by spectroscopic variations which render it difficult to distinguish them from stars of Group II., in which the carbon flutings are bright.

THE PARIS OBSERVATORY.—The annual report for 1894 indicates a high state of activity in this institution, in many directions besides those with which occasional published papers have made us familiar. Great progress has been made with the star catalogue initiated by Admiral Mouchez in 1882, comprising 350,000 observations made between 1837 and 1881: two additional volumes will be published during the present year, and the last two in 1899; a supplementary couple of volumes, dealing with observations made since 1881, will also be issued very shortly. The number of meridian observations during last year amounted to over 18,000, while observations of sun, moon, and planets total 455. Comets, minor planets, and double stars have also received a vast amount of attention. For the great photographic chart, 278 negatives were taken during the year, and the positions of nearly 33,000 stars on various plates have been measured under the direction of Mdlle. Klumpek.

The reduction of these measures was seriously commenced in November, and up to the end of the year the measures of 11 plates, showing 1760 stars, were completely reduced. Meteorological observations on the usual plan were continued regularly.

The magnificent work on lunar photography with the equatorial coudé, as well as the spectroscopic researches of M. Deslandres, have already been referred to in our columns.

THE ACTION OF LIGHT ON ANIMAL LIFE.

ALTHOUGH a number of investigations have been made on the action of light on bacteria, very few experiments have been carried out to ascertain how direct insolation affects animals inoculated with particular disease microbes. Does exposure to sunshine increase or diminish an animal's susceptibility to disease? De Renzi was, we believe, the first to study this question experimentally, and he endeavoured to answer it as regards tuberculosis by inoculating guinea-pigs with tuberculous material. Some of the animals he kept in glass boxes exposed to the direct rays of the sun for five or six hours daily, whilst others were placed in the sunshine, but instead of glass, wooden boxes were used. De Renzi found that, whilst the guinea-pigs in glass boxes—to which, therefore, the maximum amount of sunshine had access—died after 24, 39, 52, and 89 days, those in the opaque wooden boxes died after 20, 25, 26, and 41 days. Thus it would appear that sunshine materially assisted these animals in combating with tuberculous disease, for those individuals deprived of sunshine succumbed far more rapidly.

More recently, Dr. Masella has carried out a series of similar experiments with guinea-pigs inoculated, however, with cholera

and typhoid bacilli respectively. Various points were investigated as to whether insolation *previous* to inoculation increased the animal's susceptibility to these diseases, also what was the effect of insolation on the animal after infection, and whether the same results were obtained when the temperature of the surrounding air during insolation was not permitted to rise. The toxic properties of the cholera and typhoid broth cultures employed were carefully tested, and it was ascertained that the lethal dose in the case of cholera, procuring death in twenty-four hours, was secured by employing cultures in the proportion of 0·20 per cent of the weight of the animal operated upon, whilst to obtain similar results with typhoid cultures, 0·40 per cent. of the weight of the animal was the proportion in which they had to be used.

In the case of both cholera and typhoid it was found that previous exposure to sunshine increased the animals' susceptibility to these diseases, for not only did they die more rapidly when subsequently inoculated with these cultures than the guinea-pigs similarly treated, exposed, however, only to diffused light, but they succumbed to smaller doses, and doses which did not prove fatal to the guinea-pigs which had been previously protected from sunshine. When the exposure to sunshine took place *after* infection fatal results were greatly accelerated, for instead of dying in from 15 to 24 hours they succumbed in from 3 to 5 hours. These experiments were, however, open to the objection that the accelerated lethal action through subsequent insolation might be due to the higher temperature which necessarily prevailed in boxes exposed to sunshine over those to which diffused light only was admitted. To dispose of this difficulty, boxes were constructed with double cases through which a current of water was kept circulating; in the "sunshine" boxes, as before, only glass was used, whilst in the "diffused light" boxes the outer case was made of zinc. In spite, however, of these precautions as regards temperature the results confirmed those previously obtained, the insolated animals still exhibiting the same increased susceptibility to infection from these diseases over the non-isolated animals.

Dr. Masella does not attempt to give any explanation of the remarkable results he has obtained, but we would suggest that the action of sunshine should be tried on anti-toxines. It would be of great interest to ascertain how the potency of these protective fluids outside the body was affected by exposure to sunshine, and also what result, if any, isolation had on their generation within the animal system.

We know that the toxic properties of, for example, tetanus cultures may be entirely destroyed in from 15 to 18 hours in direct sunshine at a temperature of from 35° to 43° C., and Roux and Yersin state that five hours' direct insolation greatly modifies the toxic properties of diphtheria cultures; again, Calmette has found that after two weeks' insolation the poison of the *Naja tripudians* is completely destroyed, whilst a similar exposure has a damaging effect on the poison of the rattlesnake. So far as we are aware, the action of sunshine on the immunising properties of serum has not been investigated, and its study should prove of immense interest and importance.

The results obtained by De Renzi with tuberculous infection have a practical confirmation in the acknowledged benefit which patients suffering from tuberculosis derive from residence in places such as Davos, where the maximum amount of sunshine may be secured. On the other hand, Dr. Masella's experiments leave us with an uncomfortable uncertainty as to the wisdom of basking in the sunshine. He would have us believe that his investigations explain the greater prevalence and virulence of typhoid and cholera (which he states as an accepted fact) in hot countries where the sun shines with greater power and more continuously. After all, our smoke-laden atmosphere and dreary yellow fogs may be turned to account seemingly, and the London water companies may congratulate themselves that these two water-borne diseases, *par excellence*, may be made to yield not only to efficient purifying processes at their hands, but that such an unexpected ally, according to Dr. Masella, is to be found in the limited amount of sunshine which Londoners can enjoy!

G. C. FRANKLAND.

THE CONSTRUCTION OF STANDARD THERMOMETERS.

A SERIES of important articles on the preparation and testing of standard thermometers have been communicated to the *Zeitschrift für Instrumentenkunde* by Drs. Pernet, Jaeger, and Gumlich, of the Physikalisch-Technische Reichsanstalt. The selection of the best glass, the calibration of the thermometers, the determination of the coefficients of external and internal pressure, and the verification of the principal points are fully dealt with. One source of error in thermometers as usually constructed, lies in the fact of the bulbs being blown from the tubes. The vaporisation of certain constituents of the glass during this operation leads to a difference of chemical constitution between the stem and the bulb. This may be obviated by making the bulbs out of thin walled tubes of the same kind of glass, and welding them on to the stems. As regards the depression of the freezing point, it was found by Wiebe and Schott, of Jena, that glasses containing either sodium or potassium, but not both, showed this after-effect to the least extent. In order to render the reading of temperatures accurate to within 0°·002, the length of a degree should not be less than 6 mm., and since the length of the stem cannot conveniently exceed 60 cm., the range of measurable temperature is practically limited to 100°. Stem thermometers without enamel backs or enclosing tubes were the only ones found suitable for first-class standards. When certain fixed points outside the scale were to be brought in, this was accomplished by widening out the tube above them. An equal linear division of the scale was adopted, this having great advantages over the more or less untrustworthy division by equal volumes. For calibration, threads of mercury of different lengths were cut off from the main portion and measured with micrometer microscopes, viewing them both through the face and the back of the stem. But the threads were not cut off by local heating, since that is apt to produce a permanent change of capacity. The small and almost microscopic bubble which remains in every thermometer was made use of. It was brought to the entrance of the bulb when the desired portion of the thread had been driven into the stem, and then a slight jerk sufficed to cut off the required length. To facilitate this operation, the bulb was narrowed to a neck at the entrance to the stem. As regards pressure, two factors had to be considered. The external atmospheric pressure, and the pressure of the liquid in which it is immersed, tend to compress the glass vessel and to produce an apparent elevation of temperature. The capillary pressure of the mercury, and its hydrostatic pressure, on the other hand, tend to widen the bulb and produce an apparent cooling. The first of these elements was investigated by exposing the thermometer to various high and low pressures in a glycerine bath, and the second by observing the readings when the thermometer stood horizontally and vertically respectively, at its highest measurable temperature. The capillary pressure was found to be too capricious to be accurately measured, but it is a negligible quantity. The coefficient of apparent expansion of mercury in the new Jena glass thermometer 16^{III} was found to be 0·0001571 between 0° and 100°.

THE INFLUENCE OF MAGNETIC FIELDS UPON ELECTRICAL RESISTANCE.

IT is well known that the resistance (R) of a wire of bismuth, as measured with a constant current, increases under the influence of a magnetic field, and that this increase depends on the strength of the field and its direction with reference to the current in the wire. If the current traversing the bismuth is oscillatory, the resistance has a value O outside the magnetic field, or in a field in which the lines of force are parallel to the wire which is less than R. If, however, the wire is perpendicular to the lines of force of a field greater than 6000 C.G.S. units, the resistance O is greater than R; the difference O - R increases from this point pretty rapidly as the strength of the field increases. These changes are not due to alterations in the self-inductor, since they are independent of the form of the bismuth spiral. This curious phenomenon has lately been examined by M. I. Sadovsky (*Journal de la Société Physico-Chemique de Russe*, xxvi. 1894, and *Journal de Physique*, April 1895), who sums up the results of his experiments as follows: (1) The difference in the resistance of bismuth observed with constant or alternating currents is measurable outside a magnetic field with 300 alternations per second, and can be detected in magnetic fields with only three or four alternations per second; (2) this difference depends on the number of oscillations per second, and without the magnetic field increases with the increase in the frequency of the alternations; (3) the resistance which bismuth, in a strong magnetic field, offers to an increasing current is greater, and that to a decreasing current less than the resistance for steady currents. The difference between the resistances to an increasing and decreasing

current increases with the rate of change in the strength of the current $\left(\frac{dC}{dt}\right)$, and this difference is more marked with strong currents than with weak. Thus M. Sadovsky has discovered the remarkable fact that for variable electric currents the resistance of bismuth changes with any change in $\frac{1}{C}$ or $\frac{dC}{dt}$ where C is the current. The author mentions that the effects observed cannot be due to self-induction, or they would occur when the bismuth is not in a magnetic field. In a note on the above paper in the *Journal de Physique*, M. Sagnac considers what would happen if the same series of experiments were repeated with an iron wire. A straight cylindrical iron wire becomes, when traversed by a current C, circularly magnetised; the energy due to this magnetisation being, according to Kirchhoff, $\pi\kappa l C^2$, where κ is the susceptibility and l the length of the wire. This energy may possibly increase the coefficient of self-induction by $2\pi\kappa l$. From Klemenčič's data the order of the change in the apparent resistance can be calculated. For weak magnetic fields in which κ has a large value, the difference between the value of the apparent resistance for steady currents and for increasing currents may amount to several hundredths of the value of the resistance for steady currents.

TONBRIDGE SCHOOL LABORATORIES.

I HAVE often been asked to give some account of the laboratories at Tonbridge School: and as they represent some ten years of pleasant labour on my own part, and a considerable expenditure, joined with much sympathy and help from the Governors of the School (the Company of Skinners), I feel it a privilege to do so.

It is difficult to render the subject interesting to those who are not concerned in teaching, although as an instance of an ancient foundation lending itself to the most modern of claims, it may appeal to a wider circle. I must ask to be excused from entering upon any treatment of the well-worn subject, scientific education. I am not quite sure that it is any business of mine. In course of time, no doubt, a condition of stable balance will be reached, as regards the relative weight and value of the various school subjects. Those who are in the thick of the fight cannot always tell which side is winning.

So far we have little at Tonbridge beyond the training-ground itself, consisting of laboratories and workshops, which may be mentioned in sequence as follows:—

Wood Workshops.
Metal Workshops.
Mechanical Laboratory.
Physical Laboratories.
Chemical Laboratories.
Engine-rooms with electric light plant.
Biological Laboratory and Museum.

A description of these in detail is given herewith.

Wood Workshops.—These shops are well lighted and airy, occupying a ground space of 48 feet by 30 feet. Work-benches to the number of sixteen, with appropriate fittings, allow about sixty boys to work at the same time. A skilled carpenter is always in attendance for teaching his craft, and a course of graduated tasks are exacted before a pupil is allowed to construct the shelves, boxes, coal-boxes, tables, and other articles which form the staple produce of school shops.

Metal Workshops.—The wood workshops lead on to the metal shops, in use as well as in fact. They are under the care of a practical instrument-maker, and the physical laboratory owes much to his skill. It may be mentioned here that no physical laboratory can be considered complete unless it is in connection with suitable workshops wherein instruments may be constructed and repaired. These shops are devised to accommodate about twenty boys working together. They are fitted with all the necessary appliances, including planing and drilling machines and six lathes (from 4 in. centre up to 7 in.). The ground space devoted to metal work is 40 feet by 20 feet. After a course of woodwork, boys are taught to make their own tools, forging and tempering them themselves, to use the file properly, to turn, and afterwards to construct such instruments as they may fancy, it being always required that a working drawing should be made beforehand. The favourite occupation is the construction of electric bells, small dynamos, microscopes, and levels.

Mechanical Laboratory.—This room, which measures 40 feet by 21 feet, is fitted for those important lessons in accuracy of observation to which I give the name of Elementary Physical Measurements, *i.e.* the measurements of length, mass, and time, and for Practical Mechanics, *i.e.* the simpler measurements of forces and the conditions of equilibrium, the measurement of gravitation, and observations of the general properties of matter and the behaviour of matter under stress. All the work-tables are movable, and the walls are fitted with brackets and boards for the support of models and apparatus.

Physical Laboratory.—This laboratory opens out from the Mechanical Laboratory, and like it is well-lit and lofty. It is 42 feet long and 30 feet broad. The centre of the room is fitted with five solid benches attached to the floor and provided with gas. These benches are arranged to enable elementary classes to work together at the same experiment. With this object, drawers in the benches are stocked with a large quantity of apparatus which enables a class of twenty-four boys to work together through a long series of experiments in practical physics. Each experiment has to be represented by at least twelve sets of apparatus for this purpose, and some years have been occupied in organising this branch of work. The work-benches along the walls of the room lend themselves to the more advanced work in practical physics. It is needless to say that here the apparatus is not twelve-fold. Beyond the physical laboratory is the science master's private room, which has a tendency to shape itself as an advanced physical laboratory.

Chemical Laboratory.—This is a fine room, with both skylight and side windows. It is 45 feet long, 30 feet broad, and 30 feet high. Eight benches are fixed, two abreast, across the room, allowing the greatest possible freedom of movement. The benches are arranged to admit forty-eight students working together. They are fitted with shelves for reagents, fixed across the bench, and not lengthways, whereby reaching over one's work is avoided, and also a more complete view and control of the whole room is possible for the master. Each student is provided with a most efficient draught-box, serving also as a support for the vessels he is using. This arrangement keeps the laboratory thoroughly free from fumes, in spite of all well-meant efforts to the contrary on the part of pupils. The shelves and draught-boxes are removable from the benches, so that a clear space can be obtained when required for setting up apparatus on an extensive scale. The wall space is occupied by shelves for reagents, and by lead troughs for washing-up purposes. By this arrangement of confining the water-supply to the walls of the room, most of the ordinary splashing and untidiness of laboratories is avoided. The transverse arrangement of the benches reduces to a minimum the walking about occasioned by this plan. The cupboards and drawers of these benches recede, so that it is possible to sit close up to one's work. A balance-room, 30 by 15 feet, leads out from the laboratory, and beyond this is a large theatre or lecture-room capable of seating about 150 boys. The balance-room is provided with chemical balances and books of reference. The lecture-room has a suitably furnished lecture-table, blackboards, screen for lantern, and cases of minerals and chemical specimens.

Engine and Electric Light Rooms.—The electric light, being used for the main portion of the school, puts the Science Department in possession of valuable plant. A gas-engine of 12 indicated horse-power, and a reserve steam-engine of 6 indicated horse-power, fitted with a Crosby indicator, together with dynamos and accumulators, give plenty of opportunity for gaining a practical knowledge of electric engineering. In addition to this, the current obtained is most useful in providing means for practical work and testing in the physical laboratory. The electric light is also used with the mirror galvanometer, to the great advantage of cleanliness and convenience.

Biological Laboratory and Museum.—It is appropriate that the description of this laboratory should come last. It is one of the most recent additions to the school, and it should undoubtedly be the last laboratory for the schoolboy to enter. Biology, unless it is approached through a training in physics and chemistry, is not to be considered as a suitable subject for preparatory education. The roots of biological sciences must always be in physical and chemical ground.

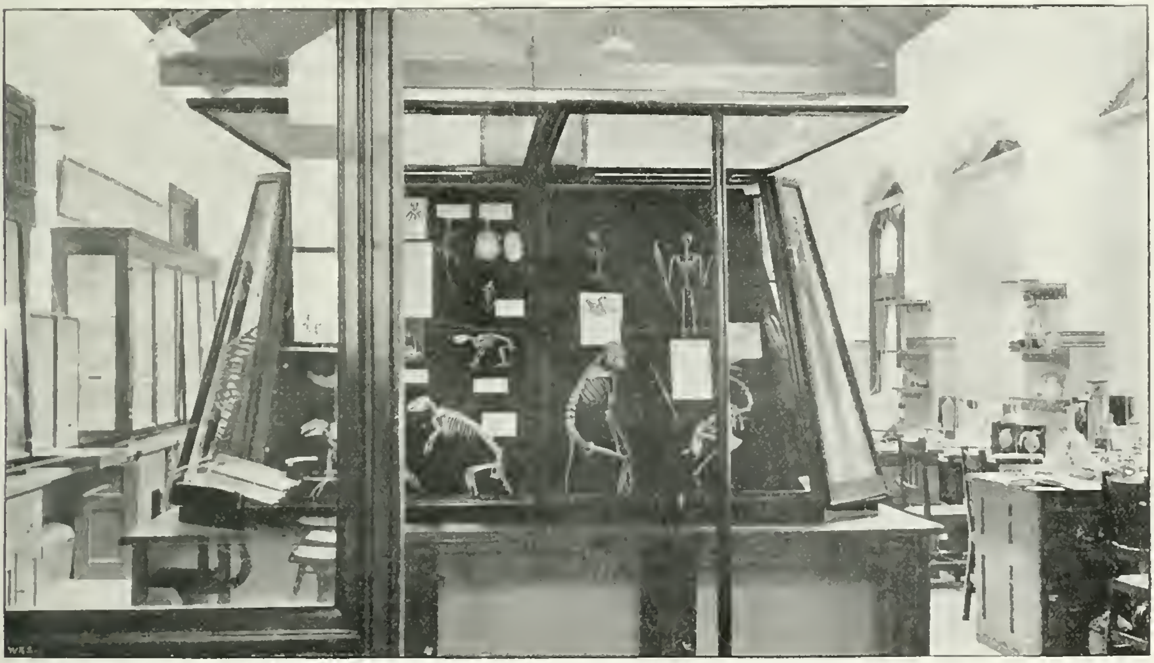
The room devoted to this work is carefully planned to ensure the most perfect light. The work-benches face windows which come down to the level of the benches, and in the roof is fixed a good skylight. The work-benches are formed of plate glass, gently sloping at the back into a white glazed gutter running into large white-ware troughs or sinks. Water-supply is at the hand of each worker, and the benches can be kept continually flushed and clean. Standing away from the work bench is the small writing-table and cupboard, &c., of each student. The arrange-

ments are peculiar, but—I may be allowed to say—most successful. The greater part of the room, which is 40 feet long by 21 feet wide, is occupied by cases which contain preparations and specimens under the headings of (*a*) Form and Locomotion, (*b*) Alimentation, (*c*) Circulation and Respiration, (*d*) Nervous System and Sense Organs, and lastly, objects displaying the main lines of classification. In fact, a collection modelled, both as to cases and modes of display, on the same lines as the admirable Introductory Collection of Sir William Flower at the Natural History Museum. It is, of course, on a miniature scale, and it is not yet complete. Beyond the main laboratory is a smaller room temporarily occupied for another purpose.

It now remains for me to add some attempt at a description of the general appearance of these laboratories. In the main, one may say, there is an air of dignity about the lofty and well-proportioned rooms, with their substantial and costly fittings. The woodwork is pitch-pine topped everywhere by thick teak. In the biological museums the cases are of mahogany, and perfectly constructed. Most of the teak tops of benches and tables are thinly coated with paraffin as a preservative. It is still important that rooms devoted to scientific work in schools should be exceptionally neat and bright in appearance. Indeed, it may even be said that appearances are at present more important than anything else as regards the value attached to the subject. Manners must grow to match the clothes. We have to bear in mind that we labour in the cause not of science alone, but of science as an instrument of school training. The laboratories are all *en suite*, whereby control is more easy, and a feeling of organic unity gained. Moreover, the workshops are within touch of the laboratories, as is also the large drawing-school.

Finally, I may mention that all the water and waste system has been laid down in direct contravention of all the best traditions of plumbing, with the happy result that we never need the services of a plumber for repairing.

ALFRED EARL.



A Case of Specimens in Biological Laboratory, illustrating Form and Locomotion.

THE DEVELOPMENT OF THE EXPERIMENTAL STUDY OF HEAT ENGINES.[1]

IT was Mr. Forrest's intention that the annual lecture bearing his name should illustrate the dependence of the engineer in his practical professional work on the mathematical and physical sciences. It therefore naturally takes the form of a review of some branch of engineering with special reference to the scientific principles which have been factors in its advancement.

Twenty years ago, Lord Armstrong stated that of all the coal raised in this country about one-third was used for household purposes, one-third for generating steam, and one-third for iron-making and manufacturing processes. He remarked that in the two first divisions the waste of fuel was shameful, and that without carrying economy to extreme limits, all the effects now realised from the use of coal could be obtained by an expenditure of half the quantity. The improvement of the steam engine is mainly due to an incessant attempt to diminish the waste of fuel.

Tests of Steam Engines in Cornwall.

Steam engineers have been face to face with the problem of economy for more than a century. Coal was excessively dear in Cornwall, and as the mines were deepened and more power was required, the cost of working increased ruinously. By reducing fuel cost, Watt saved the mining industry from extinction, and he adopted the plan of taking in payment for his engines a sum reckoned equivalent to one-third of the fuel saved. By agreement with the miners, tests were made, and the standard duty of a Newcomen engine was fixed at 7,037,000 foot lbs. per bushel. Regular duty determinations were made for all Watt's engines. Generally they gave a duty of 20,000,000. When Watt's connection with Cornwall ceased in 1800; the duty determinations were neglected, and the engines deteriorated.

Then Captain Joel Lean, who had reorganised the machinery at one of the mines, and effected great economies, started again the system of duty trials. He and his sons carried on the work for many years, and published reports of the results of the trials. Of these reports Dr. Pole says: "The publication produced an extraordinary effect in improving the duty of the engines. Engineers were stimulated to emulation amongst themselves. The practice of reporting is thought to have been attended with more benefit to the county than any other single event excepting only the invention of the steam engine itself."

I shall show later that the creation of a new and more scientific system of testing by Hirn and his colleagues in Alsace, in 1855, was the starting-point of a similar process of improvement. Quite lately there has been a revival of careful and independent engine testing and of the publication of the results, and records have been established which would have been thought impossible ten years ago.

The peculiar character of the load against which the Cornish

[1] Abstract of the "James Forrest" Lecture, delivered at the Institution of Civil Engineers, May 2, by Prof. W. C. Unwin, F.R.S.

engine worked, the lifting of a heavy mass of pump-rods, contributed to force the use of expansive working. To work without shock, a large initial and gradually diminishing effort was necessary. The extraordinary economy obtained was due probably in part to the special action of the steam, the Cornish engine being virtually a compound engine, and the admission surface being protected from cooling to the condenser: partly to the great effectiveness of a steam-jacket in an engine which worked slowly and with pauses at the end of the stroke, partly to the small clearance and separate admission and exhaust valves. The lesson engineers should have learned from Cornish experience was that in restricted conditions high ratios of expansion were economical. In this case, as in others, later engineers generalised too crudely, and concluded that expansive working was always economical. A new scientific investigation was required to correct the error.

Experiments on Boilers.

To generate steam power economically the boiler must be efficient, and the engine must be efficient, and the conditions of efficiency of boiler and engine are completely independent. Hence the early method of Watt, in which attention was paid only to fuel used and water pumped has been replaced by a method of independent boiler and engine testing. The boiler uses coal and generates steam; the engine uses steam and generates power. The economy of the boiler is reckoned on the fuel; that of the engine on the steam.

Different coals, at any rate the better kinds of coal, do not differ much in absolute calorific value. Used in boiler furnaces, they differ more, partly from differences of mechanical aggregation, but chiefly because the more bituminous coals require a larger air supply for tolerably smokeless combustion than those which consist chiefly of fixed carbon. The greater excess of air involves greater chimney waste. It is to test the commercial calorific value that Prof. Schroter has established in Munich a heat laboratory where fuels can be tested on a large scale and under ordinary practical conditions of combustion. The arrangements permit the determination of the exact conditions most suitable for each fuel.

An enormous number of boiler trials have been carried out, but most of them are mere individual tests of very little scientific value. Engineers have been too much under the impression that the evaporation depended chiefly on the type or proportions of the boiler, or the arrangement of the heating surface. But there are no obscure or complicated actions concerned in generating steam. Boilers of all types give nearly the same results, provided only proper conditions of combustion are secured. They may differ in cost, in durability, in convenience, but in efficiency they differ less than I think is commonly assumed. The following table shows that boilers of extremely different types, with very different proportions of heating surface and very different rates of combustion, and even with different coals, have all reached evaporations of from 11 to 13 lbs. of water from and at 212° per pound of coal:

Boiler Trials.

Type.	Ratio of grate to heating surface.	Coal per sq. ft. of grate per hour.	Evaporation from and at 212° per lb. of coal.	Coal.
Cornish		7·2	11·0	Welsh
Lancashire	1 : 30	22·9	11·2	Lancashire
Galloway	1 : 24	8·5	11·6	Anthracite
[illegible]	1 : 60	12·8	11·8	Welsh
[illegible]	1 : 46	10·8	11·0	Anthracite
[illegible]	1 : 38	8·9	11·8	..
[illegible]	1 : 34	22·4	12·0	Welsh
..	1 : 50	25·5	12·5	Lancashire
[illegible]	1 : 70	7·7	13·4	Welsh
..	1 : 61	18·6	12·5	..

Mulhouse Trial of 1859.

The earliest boiler trials carried out in a completely satisfactory way were those made by the Société Industrielle of Mulhouse in 1859. The Society offered a prize to the maker of any boiler which would evaporate 1800 lbs. per hour, at 75 lbs. per square inch pressure, and which would evaporate 9·1 lbs. of water, from and at 212°, per pound of Alsatian coal of not very good quality. With the coal used in these trials, 130 cubic feet of air per pound of coal are chemically necessary for complete combustion. It was found that the reduction of the air supply almost to this limit, and to a point at which there was definitely incomplete combustion, reduced the chimney waste and increased the efficiency of the boiler. In two special trials, each of a week's duration, the evaporation was 9 lbs. with 331 cubic feet of air, per pound, and 9·53 or 6 per cent. more with 247 cubic feet.

The determination of the air supply to a boiler is not altogether an easy operation. An anemometer was used in Alsace, and in suitable conditions it will give approximately accurate results. In recent trials chemical analyses of samples of the furnace gases have been made, and the amount of air supplied calculated from the percentage of CO_2. This method is accurate in principle, but the samples analysed are a very minute fraction of the total chimney discharge, and the samples may not be average samples. In some trials in which this method has been used, there are discrepancies in the ratio of the chimney loss and the undetermined loss, chiefly due to radiation, difficult to understand. Neither anemometer nor chemical analysis is suited to serve as a means of regulating the air supply in the ordinary working of a boiler. What is wanted is an instrument as easily read as a pressure gauge, and giving continuous indications.

The Dasymeter.

The dasymeter, invented by Messrs. Siegert and Durr, of Munich, is a fine balance in an enclosed case through which a current of the furnace gases is drawn. At one end of the balance is a glass globe of large displacement, at the other a brass weight. Any change of density of the medium in the chamber disturbs the balance. A finger on the balance moving over a graduated scale gives the amount of the alteration of density. An air injector draws the furnace gas from the flues, and it is filtered before entering the balance case. An ingenious mercurial compensator counterbalances any effect due to change of temperature or barometric pressure.

The dasymeter is usually combined with a draught gauge, and an air thermometer or pyrometer in the flue is required if the amount of waste heat is to be calculated. The dasymeter requires, initially, exceedingly delicate adjustment, and its indications must be checked from time to time by a Bunte's burette. It is set to read zero with pure air, and then any increase of density due to CO_2 is read as a percentage on the scale. When in adjustment, it is as easy to read the percentage of CO_2 in the furnace gases as to read the pressure on a pressure gauge. When the dasymeter is fitted to a boiler, the stoker has directions to adjust the supply of air so that the furnaces gases have about 12 per cent. of CO_2. With practice he learns what alterations of the damper or fire-door, or thickness of fuel on the grate, are necessary, or whether an alteration of grate area is desirable. After a little time the percentage of CO_2 can be kept very constant.

Isherwood's Experiments on Marine Engines.

About the year 1860, Mr. Isherwood, Chief Engineer of the United States Navy, began a series of systematic tests of engines and boilers on a very large scale, and with resources only available in a Government establishment. The trials were made with skill and determination, and the substantial accuracy of the results, startling as they were, has never been questioned.

All Isherwood's trials of large marine engines showed that when expansion was extended beyond exceedingly small limits, it caused not an economy, but a waste. In his second volume he sums up his results as proving that when cut-off is earlier than 0·6, or perhaps even 0·7 of the stroke, the consumption of steam reckoned on the work done is increased. Curiously enough, this led him to attack the compound engine. From the quantities in the table of experiments, he says, "it will be seen how useless in point of economic gain is the preposterous arrangement of steam engine known as the double cylinder, Woolf, or Hornblower engine. . . . Opposed to these facts, the declarations of interested patentees and engine builders must be classed in value with those set forth by quacks in advertisements of their nostrums." This is from a paper dated 1865, and it is curious, because Isherwood generally saw clearly enough the danger of drawing sweeping conclusions from narrow experimental premises.

The proper lesson from Isherwood's results was merely that

certain conditions must be observed to secure economy in expansive working. Unfortunately, more generally the conclusion was drawn that the Cornish results were not to be trusted, and that expansion was not economical, and Isherwood's own language lent authority to the least accurate view of his results. To obtain greater insight into the true action in the cylinder, and to find a reconciliation of the Cornish and American tests, experiments of a much more refined character were wanted and insight due to wider scientific knowledge.

The Physical Properties of Steam.—Regnault.

No useful progress could be made with a theory of the steam engine, no accurate reduction even could be made of the results of engine tests without exact determinations of the relations of pressure, temperature, volume, latent heat and liquid heat of steam. It was fortunate, therefore, that about 1840 M. Regnault obtained the means from the French Government to make a series of researches on the physical properties of steam with splendid instrumental appliances. He wisely carried out his determinations over a very wide range of conditions, and spared no labour or trouble in attaining accuracy. Regnault's results were of the greatest importance as a foundation for accurate study of the steam engine.

The Foundation of Thermodynamics. Carnot and Joule.

The next important step was the discovery of the equivalence of heat and work. Joule's investigations began with an attempt to improve Sturgeon's magnetic engine. He was so led to consider motive power problems from the engineer's standpoint, as a question of duty, or of something obtained for something expended. He ascertained the amount of electric current produced by the chemical combustion of a given amount of zinc, and comparing his results with those obtained in good steam engines, he concluded that, making the largest allowance for possible imperfections of his magneto engine, it was never likely to be a rival in economy to the steam engine. That was a negative but a useful result. It closed one direction of useless endeavour only too likely to attract the inventor.

One of the effects of electric action which Joule noticed was the heating of his conductors, and it was to the measurement of this heating effect he next addressed himself. The heat developed in the conductor by the electric action due to elements combining in the galvanic cell was found to be identical with that which would be generated by the direct combustion of the same elements. Finally, he came to consider the relation between the mechanical work expended in driving a magneto electric machine, and the heat developed in the external circuit of the machine. He concluded that for 838 foot lbs. expended a pound degree of heat was generated. Later experiments corrected this value, but the discovery of the equivalence of heat and work was made.

As early as 1824, twenty years before Joule's discovery, Sadi Carnot, in a remarkable pamphlet on the "Motive Power of Heat," demonstrated the fundamental principle that the amount of work obtainable from any given quantity of heat cannot exceed a quantity proportional to the fall of temperature. Unfortunately adopting, though with hesitation, the view held in his time that heat is material and indestructible as heat, he coupled with his true principle the false corollary that all the heat entering an engine is discharged in the condenser. Joule, in 1845, found this principle of Carnot, and looking to the corollary as essential, supposed the principle itself to be false. He failed to perceive that Carnot's principle was the essential supplement to his own discovery, and that it showed why the apparent efficiency of the steam engine is so low. It took six years before Joule's and Carnot's principles were reconciled, and for three of them even Lord Kelvin refused to accept Joule's discovery, because it apparently conflicted with the principle of Carnot.

The Founders of the Rational Theory. Rankine, Clausius, Zeuner.

The impetus given to the study of thermodynamics by the discovery of Joule, and the perception of the fundamental importance of Carnot's theorem, was enormous. Heat problems could now be brought out of the region of mere empirical solutions, and treated from the rational standpoint of an exact science, and the steam engine, as the most important example of heat transformation, attracted at once the attention of scientific men of commanding intellectual ability. In a very few years Rankine and Clausius had built up a strictly rational mathematical theory of the steam engine, and, a little later, Zeuner carried further the analysis of some of the more subordinate details. The theory with one exception, to be referred to presently, took account of all the actual conditions under which steam is used, and furnished exact rules for the relation of steam expended and work done for all arrangements of the actual steam engine practically adopted.

It was just at this time that the experiments of Isherwood were published, and a comparison of experimental results and theoretical calculations showed directly a very large discrepancy. The steam consumption in some trials was 30, 40 or 50 per cent. more than it should have been in the assigned conditions of working according to the rational theory. Some action of quite governing importance had obviously been neglected in the theoretical analysis.

The Experimental Theory.—Hirn and the Alsatian School.

A year or two before Isherwood began his experiments, an Alsatian engineer, M. Hirn, had discovered and measured cylinder condensation.

Joule's discovery attracted Hirn's attention, and he set to work in 1854 to verify, by an exact engine test, whether the difference between the heat received by an engine and discarded in the condenser was the equivalent of the work done. His two most important memoirs relating to the steam engine, are a memoir on the utility of steam-jackets in 1855–6, and another on the use of super-heated steam in 1857. In these researches he devised a method of accurate engine tests, involving the measurement of all the quantities of heat received by or rejected from the engine, which, with hardly any change at all, is the method of accurate engine testing adopted ever since. Under his influence and direction, engine tests were carried out in Alsace for many years, and the results exactly analysed. It may be recalled that the admirable series of engine tests, the first tests in which the heat quantities were accurately measured in this country, which were made by Mr. Mair Rumley, and described in three papers on "Independent Engine Tests" in the *Proceedings* of this Society in 1882, 1885, and 1886, were trials carried out strictly in accordance with Hirn's methods.

As with Lord Kelvin, so with Hirn. It was the recognition of an apparent conflict of Joule's discovery with Carnot's law which first attracted his attention. It was the attempt to determine whether part of the heat supplied to an engine disappeared as work which determined the form of his trials. His experiments of 1854 showed that "heat in a steam motor is not only dispersed, but actually disappears, and the power obtained is exactly proportional to the heat which disappears as heat to reappear as motive power." Some rather later and more careful experiments enabled him to verify Joule's equivalent by the actual results of a large engine test to an accuracy of about one per cent.

The discovery of initial condensation, and the proof of the powerful action of a small amount of heat transmitted from the jacket, both pointed to the conductivity of the cylinder wall as the cause of the large waste of steam which the constructors of the rational theory had neglected. The cylinder is cooled during expansion, and still more during exhaust by an action analogous to internal radiation to the condenser. Before any work can be done in the next stroke, the wall has to be reheated by condensing fresh steam. The extreme facility with which steam yields or abstracts steam by condensing and evaporating, accounted for the rapidity of the action. The magnitude of the condensation increases with the range of temperature to which the cylinder wall is subjected. It is larger in condensing than in non-condensing engines, and larger with high ratios of expansion.

Some time ago I ventured to say that there was no trustworthy engine test which showed that the consumption of steam with a jacket is greater than without the jacket. I believe that is still true, but undoubtedly the economy due to the jacket varies in different cases from 30 per cent. to very nearly zero. Roughly, the jacket is more useful with small engines than with large; with slow engines than with fast engines; but all this amounts to little more than saying that the jacket is most useful in those cases where the initial condensation is largest. Just in proportion as the engine, whatever its type, is of the highest class and most scientific design, the jacket is less useful.

The jacket reduces, but it does not prevent initial condensation. Hirn looked for some more powerful way of heating the

cylinder wall without causing condensation: he found it in super-heating. He constructed, in 1855, a super-heating apparatus in the flues of the boiler at Logelbach, which still exists. The experiments with super heated steam were carried out between 1855 and 1856, and showed clearly the effectiveness of the method in reducing condensation. Super-heating came largely into use in the years 1860-70 in this country in marine engineering, the practice having been introduced here by John Penn. In every case in which it was used an economy of coal was realised. Generally the economy amounted to from 15 per cent. to 20 per cent. It was ascertained that this was due strictly to economy of steam, and not to the utilisation in the boiler of heat previously wasted. But the use of super-heated steam in this country was gradually abandoned, partly no doubt from some practical difficulties, but chiefly, I believe, because practical engineers had no clear idea why super-heating should produce so large an economy, and they were not indisposed to abandon a complication, the action of which they could not satisfactorily explain to themselves.

No possible improvement of the steam engine, of which we have any knowledge at this moment, offers anything like so great a chance of important economy as the reintroduction of super-heating, and especially of super-heating to at least 100° or more above the saturation temperature of the steam. I obtained in Alsace on a very good 500 H.P. compound mill engine with jackets, and every appliance for economical working, an economy of 15 per cent. Mr. Mair Rumley has fitted a super-heater to a Babcock boiler supplying a triple engine, and has obtained an economy of 10 per cent. In both cases the economy is economy of steam, and therefore is not due to any increase of boiler surface or increase of efficiency in generating the steam. Lately Prof. Schröter, of Munich, has been experimenting with a small special compound condensing engine of only 60 I.H.P., running at the moderate piston speed of 380 feet per minute, and with the not excessive boiler pressure of 165 pounds per square inch. The H.P. cylinder is not jacketed. The L.P. is jacketed with receiver steam. In this case in a tube super-heater of a rather special construction in the uptake of the boiler, the steam is superheated to 670° F., or nearly 300° above the saturation temperature corresponding to the pressure. In two trials of six and eight hours' duration, periods quite long enough for accurate determination of results with so accomplished an observer as Prof. Schröter, the consumption of steam was only 10·2 pounds per I.H.P. hour, and the consumption of German coal of moderate quality only $1\frac{1}{4}$ pounds per I.H.P. hour. The steam consumption is the lowest on record for any engine of any type or size, and is very remarkable for so small an engine.

Conflict of the Rational and Experimental Theories.—Zeuner, Hirn, and Hallauer.

On the appearance of Isherwood's researches in 1863, the discrepancy between the rational theory and the results of experiments was recognised by Rankine and others. But the conditions of cylinder condensation are so complex, that for a long time the more theoretical writers practically ignored both Hirn's and Isherwood's results. Zeuner, perhaps, had pushed the rational theory to the furthest limit of detail, and with the greatest insight into practical conditions. But it was not till 1881 that he began to explicity admit the largeness and importance of the condensing action in the cylinder. Zeuner then was disposed to attribute initial condensation to the presence of a permanent and not inconsiderable mass of water in the clearance space of the engine. No doubt it is simpler analytically to deal with the thermal changes of the steam plus a given mass of water than with the thermal changes of steam, water, and a varying area of solid cylinder wall. In opening a discussion with Hirn in 1881, Zeuner wrote that if the presence of water in the clearance space was conceded, the Alsatian calculations would be greatly shaken, and "the enormous influence which they attributed to the cylinder wall would in future be attributed in part, perhaps chiefly, to the water in the clearance space." He thought it conceivable that in certain cases the whole of the initial condensation was due to water in the clearance space. There thus arose a rather angry controversy, which has been summed up in the question, "Is it water or iron?" I do not know that this controversy has been as yet completely decided, or that perhaps an absolute decision is possible. I cannot help thinking that Hirn, with the clearness of view due to his experimental work, had on the whole the best of the controversy, and I do not know that anything better or more instructive can be said than the words in which he finally summed up his position. "We recognise," he said, "that the interpretation of the Alsatians differs from that of M. Zeuner, not at all in that it denies the possible presence of water in the cylinder (we are not so hydrophobic), but in that it admits that the water, varying in quantity, is presented only temporarily, is carried away and renewed stroke by stroke, and acts chiefly as the medium between the steam and the cylinder wall. In the Alsatian explanation the action of the water raises the thermal action of the sides. In Prof. Zeuner's view, the water is permanently present and acts independently of the cylinder sides."

Recent Systematic Experiments. Willans.

It has been quite impossible in this lecture to do more than select one or two of the most important of the experimental investigations during the last fifty years. But I should not like to omit all reference to the two series of experiments of the late Mr. P. W. Willans. Mr. Willans' work is no doubt well known to all steam engineers, and needs no detailed description. However purely practical the object Mr. Willans had in view, his experiments were made in the true spirit of scientific research. No trouble was too much to secure accuracy to the last decimal, no possible cause of error was so trivial that its investigation was reckoned unnecessary. A few experimenters, Isherwood, Gately and Kletsch and others had made experiments on a methodical system, varying a single factor at a time. Willans carried out the method of experiments in series on a scale which, till he proved that it could be done, no one would have supposed possible. There is a series of non-condensing and a series of condensing trials; in each there are trials of simple, compound, and triple engines; and for each of these, again, trials with initial pressure varied, with expansion varied, and with speed varied. The results, tabulated in the clearest way, form a quarry of scientific data, but at present, in the main, an unworked quarry. Perhaps that statement will seem surprising, and of course I am expressing only my own view, for which I claim no infallibility. What Mr. Willans might have done had he been spared, it is impossible to say. He had the most active mind and the widest experience devoted, perhaps, at any time to the study of steam problems.

Let me protest as strongly as possible, again with the reservation that I am stating my personal view, against the tendency to suppose that the great work of Willans can be summed up in a so-called Willans' law, or that that law, handy as it may be for practical steam engineers, is more than a quite subordinate part of Willans' work. The Willans' law is nothing more than the empirical descriptive statement that the relation of total steam consumption and indicated or effective horse-power can be very approximately expressed by a linear equation, for the case of an unjacketed engine working with a fixed cut-off. Further, nothing is done in Willans' papers to fix what is the linear equation for any given engine. So far as those papers go, and until some kind of theory taking account of initial condensation is discovered, we can only find the relation of steam consumption and horse-power for any given engine by making two accurate trials of the engine itself. Willans' law leaves us in regard to any given engine in the same position as an astronomer with a new comet. When the comet has been observed for a sufficient period, and some of its positions fixed, a probable orbit can be calculated. The straight-line law leaves the steam consumption of a new engine as unknown as the elliptic law the orbit of a new comet.

Willans himself says nothing whatever as to any possible rational basis for the Willans' law. He put it forward purely as the result of plotting his experiments. Later, Captain Sankey showed that the total steam consumption of an engine working adiabatically with fixed ratio of expansion would also follow nearly but not exactly a straight-line law if all clearance losses, radiation, and exhaust waste and back pressure loss were neglected.

If we assume isothermal expansion (and really so far as the area of the diagram is concerned, it matters little what law of expansion is assumed), it is easy to find a formula for the total steam consumption of an engine working without clearance loss or exhaust waste. I have found such a formula, and plotted the results both for a condensing and a non-condensing engine in the diagram. It is found that the lines plotted are not exactly, but very nearly, straight lines. That carries us a certain way, but it is an enormous jump to assume without examination that the steam wastes in the engine, amounting to from 20 to 50 per cent. of the steam used, and arising from causes of the most com-

plex kind, depending on the volume of the clearance, the action of the cylinder wall, the loss of the toe of the diagram, the waste expansion between the cylinders, and other causes of loss, that these also can be expressed as a simple linear function of the horse-power.

Now, in the first edition of his treatise on the steam engine, which appeared in 1878, Prof. Cotterill had seriously attacked the problem of cylinder condensation from the theoretical side. Prof. Cotterill found it possible to give a partly rational, partly empirical, formula for cylinder condensation.

But, according to his formula for unjacketed simple engines, the initial condensation has a fixed ratio to the steam present at cut-off. In the diagram, lines for steam present at cut-off are given, calculated in the manner already described. Above these has been set up the condensation by Cotterill's law, and the total steam consumption at various loads is then given by a line very nearly straight and closely agreeing with a Willans' line.

The curves on the two diagrams agree well with Willans' results, and they differ from Willans' lines in being obtained entirely by calculation without experimenting on the engine. It would not be right to make too much of the coincidence, but I thought it would be interesting to show that theory and experiment converge. A good deal has yet to be explained, but the discussion in Prof. Cotterill's treatise has done more than anything else to throw light on the conditions which promote or hinder cylinder condensation, and on the means useful in securing economy of working.

Since 1845, purely scientific men, scientific experimenters, and practical engineers have all been engaged in the study of the steam engine. I do not believe that any one of the three can claim all the credit for the improvement of the steam engine to the exclusion of either of the others.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—At a Congregation of the University held on Tuesday, 21st inst., the proposed Statute on Degrees for Research was passed in its final form, *nemine contradicente*. It only remains for the Statute to be passed by Convocation, and it will come into force.

At the same meeting, the addition to Statute conferring the title of Professor of Anthropology on Dr. E. B. Tylor, so long as he shall hold the office of Reader in Anthropology, received the final sanction of Congregation. A proposal recognising Anthropology as a subject for the Final-Honour School of Natural Science was then brought forward. After some debate the preamble was passed. Placets 24, non-placets 16.

Cambridge.—The following is the Speech delivered by the Public Orator, Dr. Sandys, in presenting for the honorary degree of Doctor in Science, Mr. Francis Galton, F.R.S.

Sedes olim sibi notas hodie revisit alumnus noster, qui flumine Nilo quondam explorato, et Africa Australi postea perlustrata, velut alter Mercurius omnium qui inter loca deserta et inhospita peregrinantur adiutor et patronus egregius exstitit. Idem, velut alter Aeolus, etiam ipsos ventos caelique tempestates suae provincae audacter adiunxit. Hodie vero Academiae nemora nuper procellis nimium vexata non sine misericordia contemplatus, e frondibus nostris caducis capiti tam venerabili coronam diu debitam imponi patitur. Tempestatum certe in scientia iamdudum versatus, ventorum cursus tabulis fidelibus olim mandavit, gentesque varium caeli morem praediscere docuit, laudem philosopho cuidam antiquo a Nubium choro Aristophanico quondam tributam uno saltem verbo mutato meritus: *οὐ γὰρ ἂν ἄλλῳ γ' ὑπακούσαιμεν τῶν νῦν μετεωρολογούντων.* Longum est avorum et proavorum ingenia magna in ipsorum progenie continuata ab hoc viro, Caroli Darwinii cognato, virorum insignium exemplis illustrata percensere. Longum est tot honores titulosque ab ipso per tot annos cumulatos commemorare. Hoc autem in loco, eloquentiae eius undecim abhinc annos conscio, instituti anthropologici praesidem non corporis tantum sed etiam mentis humanae mensorem appellaverim. Inter antiquos quidem celebratum erat illud Protagorae, omnium rerum mensuram esse hominem. Inter recentiores autem notum est hunc praesertim virum hominum omnium, imprimis pessimorum, mensuram ad amussim velle exigere. Ceterum plura hodie dicere supervacaneum est; constat enim ne optimorum quidem virorum a laudibus abesse debere mensuram.

Duco ad vos virum de scientia anthropologica et meteorologica praeclare meritum, caeli et terrae indagatorem indefessum, studiorum denique geographicorum etiam inter nosmet ipsos fautorem insignem, Franciscum Galton.

Lord Acton will deliver his inaugural lecture as Regius Professor of Modern History on June 11, at noon.

Prof. Lewis announces courses of lectures and demonstrations in Crystallography during the Long Vacation, beginning on July 9.

Prof. Roy announces a practical course in Bacteriology, to be given by Dr. Wesbrook and Dr. Lazarus-Barlow, in the Long Vacation, beginning on July 8. There will also be a course of lectures with practical work in Elementary Pathology, beginning on July 9.

Mr. H. F. Baker, Fellow and Lecturer of St. John's College, has been appointed University Lecturer in Pure Mathematics, in the place of Dr. Forsyth, now Sadlerian Professor.

A year ago a committee, representing various educational bodies, was formed, at the instance of the Association of Headmasters, to formulate an examination syllabus on which to award major scholarships, offered by County Councils and similar bodies, and tenable at places of higher education. All who know how very different are the scholarship schemes of the County Councils, agree that a larger degree of uniformity should prevail in the examinations held for the purpose of selecting candidates for the scholarships. The Association's scheme for major scholarships has been so drawn up that only candidates showing ability and intelligence distinctly above the average can be elected. Candidates must not be more than eighteen years of age in case of boys, and nineteen years in case of girls, and must have passed a preliminary examination to test their general education before they can compete for the scholarships. The scheme provides that the final scholarship examination shall consist of three groups—science, commercial, and literary—each containing obligatory and optional subjects. The subjects of examination for science scholarships have been carefully selected, and with due consideration to the claims of practical work.

The second annual report of the Technical Education Board of the London County Council appears in the *Technical Education Gazette*. A sum of nearly £15,000 was granted, during the year covered by the report, to intermediate and secondary schools. The fact that the Board has now over six hundred scholars attending these schools indicates how seriously it is concerned with technical education. While the question of the Teaching University for London has been in abeyance, the Board has not been able to act upon the proposal in Mr. Llewellyn Smith's report to contribute £10,000 a year towards the technical departments of the University. It was thought undesirable, however, to wholly abstain from helping institutions of university rank until the establishment of the Gresham University, so a grant of £1000 was made to University College, and £500 to Bedford College. The polytechnic institutes are rapidly increasing in extent and advancing in efficiency. The total annual expenditure of the eight institutions open last year amounted to about £90,000, their total number of students to over 27,000, and their aggregate number of separate classes or courses of lectures to over 1250. It is believed that the polytechnics now give probably nine-tenths of all the evening instruction in technological subjects in London, and three-fourths of the evening science instruction. All this represents an immense advance on the state of things five years ago, and indicates that the Board has remarkably extended the facilities for technical education during the two years it has been at work.

The fourth annual report (2 vols.) of the U.S. Commissioner of Education has been received. The volumes provide a mine of information on educational methods in France, Austria, Germany, Sweden, Switzerland, Alaska, the United States, and our own country. A full account is given of the character and development of German Universities, by Prof. Paulsen, of Berlin, supplemented by a statistical review of the subject by Prof. Conrad, of Halle. School museums in various parts of the world form the subject of a separate chapter. There is also an elaborate paper in which methods of physical training are very fully treated.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, vol. i. No. 7, (April 1895).—"Riemann and his significance for the development of modern mathematics," is the translation, by A. Ziwet, of an address delivered by Prof. F. Klein at the general session of the Versammlung Deutscher Naturforscher und Aerzte in Vienna, September 27, 1894. In it the author attempts to give an idea of the life-work of Bernhard Riemann, "a man who more than any other has exerted a determining influence on the development of modern mathematics."—Prof. Cajori contributes a note on the multiplication of semi-convergent series, in which, following up his work in a recent number of the *Bulletin*, he further extends results arrived at by Pringsheim (*Math. Ann.* vol. xxi. pp. 327–378) and by A. Voss (*Math. Ann.* vol. xxiv. pp. 42–47).—Mr. L. E. Dickson discusses Gergonne's Pile Problem (*cf.* Ball's "Recreations," pp. 101–6), and points out one or two slight inaccuracies in a proof given by Dr. C. T. Hudson in *Educational Times* Reprints, vol. ix. pp. 89–91.—Prof. Ziwet gives an account of the Repertoire bibliographique des Sciences Mathematiques, *i.e.* a card catalogue of mathematical literature which has been widely circulated amongst mathematicians. Notes, and new publications, as usual, close the number.

Bulletin de l'Académie Royale de Belgique, No. 3.—On Chandler's formulæ, by F. Folie. The author criticises the latest formula enunciated by Chandler for the variation of latitude. Even when compared with the Strassburg observations, which most closely accord with the formula, it is evident that the periods are not correctly rendered. The constants in the formula require further empirical research. On the equations of the physical field, by Ch. Lagrange. The form, *i.e.* the law of distribution of a quantity of matter round its centre of inertia, constitutes in physics a principle as important as the quantity of matter itself, or its mass. Besides the principle of concentration, there is a principle of direction, and the latter is as important as the former. The author investigates the equations of motion in a medium consisting of rigid points, and introduces the conception of axial matter (*matière axée*), in which account is taken not only of the mass of a point, but also of all the qualities depending upon the shape of the mass. The density of a point is simply the intensity of one of the parameters determining its action, but a large number of other parameters of known form remain to be considered. The consideration of axial matter leads in a manner analogous to that which obtains in Kelvin's theory of the intensity of magnetisation, to theorems upon wires, plates, and leaves of similar substance, and then upon bodies made up of these structures.—On the colour, density, and surface tension of hydrogen peroxide, by W. Spring. This substance, which is highly explosive in the anhydrous state, has a blue colour when seen in a thickness of 100 cm. The colour resembles that of water, but is 1·83 times as intense. The density of the anhydrous substance is 1·4996. When 60·0445 gr. of it are contained in 100 cc. of an aqueous solution, the density is 1·2540. The surface tension is 0·456, that of water being 1. The addition of 6·4 per cent. water raises the surface tension by 102·5 per cent. Action of certain hot gases upon red phosphorus, by A. J. J. Vandevelde. Retger's supposition that phosphamine is produced by passing hot hydrogen over red phosphorus is not correct. Vapour of phosphorus is formed and carried off by the hot gas, exhibiting the phenomenon of spontaneous combustion on emerging into the air. Other hot gases, such as nitrogen, CO_2, CO, SH_2 and dry HCl gave rise to the same phenomenon.

Wiedemann's Annalen der Physik und Chemie, No. 4.—On luminescence, by Eilhard Wiedemann and G. C. Schmidt. An important distinction must be drawn between luminescence due to physical and that due to chemical causes. A prolonged afterglow makes the presence of chemical luminescence very probable. Thermoluminescence occurs after the body has been exposed to a temperature far below incandescence. A phenomenon now called "lyoluminescence" occurs with some substances during solution, when they have been previously exposed to strong light. The authors show that luminescence under cathode rays is always accompanied by chemical action. Mixtures of calcium and manganese salts show luminescence phenomena of great brilliance under cathode rays, and when subsequently heated. On normal and anomalous dispersion of electric waves, by L. Graetz and L. Fomm. The dielectric constant and the conductivity of a body are not perfectly independent quantities, but are connected by the constitution of the body in a manner similar to that in which refraction and absorption are connected in optics.—Magnetisation of iron by very small forces, by Werner Schmidt. Steel obeys very small magnetising forces more rapidly than iron. The limit of proportionality between magnetising forces and magnetic moment may with practically sufficient accuracy be placed at a field intensity of 0·06. Otto von Guericke's original air pump, by G. Berthold. The pump in the Royal Library at Berlin cannot be considered as Guericke's original air pump, since the latter was bought by the Archduke of Saxony, and taken to Sweden by Dr. Heraeus, where it was used as late as 1726 as a lecture instrument. When last heard of, in 1734, it was in charge of the Professor of Mathematics at Lund.—Remarks upon Mack's paper on the double refraction of electric rays, by Wilhelm von Bezold. The different behaviour of wood towards electric radiation along and across the fibre may be shown in a variety of ways. Lichtenberg's figures on wooden plates cut along the fibre show an elliptical shape, like doubly refracting crystals. A similar phenomenon is exhibited by a plate of ebonite rendered anisotropic by sticking strips of tinfoil parallel to each other on the other side. The production of a doubly refracting or even a circularly polarising body for electric rays by embedding conducting rods in a suitable dielectric does not appear to be hopeless.

THE only article of general interest in the *Nuovo Giornale Botanico Italiano* for April is one by Dr. U. Brizi, on the disease of the vine known as *brunissure* or blackening. The plasmode found in the diseased cells of the leaves cannot, he considers, be properly referred to *Plasmodiophora*, as has been done by most authorities hitherto. It belongs to an organism which appears rather to present characters intermediate between the Myxomycetes and the Amœbæ.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, April 25.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—Action of nitroxyl on amides, by W. A. Tilden and M. O. Forster. The interaction of nitroxyl chloride and amides usually results in the exchange of the amidogen group for an atom of chlorine.—Action of nitrosyl chloride on asparagine and aspartic acid; formation of lævorotatory chlorosuccinic acid, by W. A. Tilden and B. M. C. Marshall. Asparagine and nitroxyl chloride interact with formation of Lævo-chlorosuccinic acid.—A property of the non-luminous atmospheric coal-gas flame, by L. T. Wright.—Diortho-substituted benzoic acids. (1) Substituted benzoyl chlorides, by J. J. Sudborough.—Diortho-substituted benzoic acids. (2) Hydrolysis of aromatic nitriles and acid amides, by J. J. Sudborough. In these two papers the author describes a number of new nitro- and bromo-benzoyl chlorides and benzoic acids.—Note on the action of sodium ethylate on deoxybenzoïn, by J. J. Sudborough. When deoxybenzoïn and sodium ethoxide are heated together, stilbene and hydroxydi-benzyl are produced.—A constituent of Persian berries, by A. G. Perkin and J. Geldard. In addition to the substances previously isolated from Persian berries, the authors have obtained a quercitin dimethyl ether which they term rhamnazin.—Potassium nitrososulphate, by E. Divers and T. Haga. The potassium nitrososulphates, by described Hantzsch, and by Raschig, seem to be identical with that first prepared by Pelouze. The milk of the gamoose, II., by H. D. Richmond.

May 2.—Studies on the constitutions of the tri-derivatives of naphthalene. No. 10, the dichloro-α-naphthols and trichloronaphthalenes from 3 : 4-dichlorophenyl-1-isocrotonic acid. No. 11, the trichloronaphthalene derivable from Cleve's 1 : 2 : 2-α-nitrochloronaphthalenesulphonic chloride. No. 12, the trichloronaphthalene, derivable from Alén's α-nitronaphthalene-2 : 2′-disulphonic chloride. No. 13, the α-naphthylamine-2 : 2′-disulphonic acid of Freund's German Patent, 27346. No. 14, the fourteen isomeric trichloronaphthalenes. The non-existence of a trichloronaphthalene melting at 75·5°: the formation of chloro-derivatives from sulphonic chlorides, by H. E. Armstrong and W. P. Wynne. In these six papers the authors describe thirteen out of the fourteen possible isomeric trichloronaphthalenes, together with a large number of compounds obtained during the preparation of these halogen derivatives. The solubilities of gases in water under varying pressure, by E. P. Perman. Henry's law holds for chlorine, bromine, carbon dioxide, and hydrogen sulphide, but large deviations are observed with ammonia, hydrogen chloride, and sulphur dioxide.—The existence of hydrates and of double compounds in solution.

Part 1, by E. P. Perman. From experiments on the pressure of gases dissolved in various solutions the author concludes that sodium sulphate exists in aqueous solution as the hydrate $Na_2SO_4.10H_2O$, and that silver chloride exists in ammoniacal aqueous solutions as the compound $AgCl.3NH_3$.—Derivatives of π-bromocamphoric acid, by F. S. Kipping.—Paraheptyltoluene and its derivatives, by F. S. Kipping and O. F. Russell.—Note on the formation of a phosphate of platinum, by R. E. Barnett. On passing phosphorus pentoxide vapour and oxygen over red-hot platinum, a yellow phosphate PtP_2O_7, insoluble in aqua regia, is obtained.

Linnean Society, May 2.—Mr. C. B. Clarke, President, in the chair.—Dr. O. Nordstedt of Lund, Dr. Rudolph Philipppi of Santiago, and Dr. M. Woronin of St. Petersburg, were elected foreign members. Mr. H. M. Bernard showed under the microscope the circumscribed patches of setæ above and below the stigmatæ on the pupa of the vapourer moth (*Orygia antiqua*). The arrangement suggested a vanished notopodium just where, in the Hexapods, a dorsal branch of a parapodium ought to have vanished, according to the exhibitor's method of deducing the different groups of the Arthropoda from their Annelidan ancestors, as sketched in his recent paper on the *Galeodidæ*.—Mr. E. M. Holmes exhibited some new British Algæ from Dorsetshire and Surrey; amongst others, *Ulvella confluens* and *Ectocarpus Reinholdi*, both discovered last month at Weymouth, and the latter previously known only from the Baltic.—Mr. J. E. Harting exhibited and made remarks on a specimen of *Cuculus canorus* in the rare hepatic plumage (*Cuculus hepaticus*, Sparrman), recently obtained at Bishop's Waltham, Essex.—Mr. W. T. Thiselton-Dyer, C.M.G., then gave an abstract of a paper by the late Mr. John Ball, F.R.S., on the distribution of plants on the southern side of the Alps, prefaced by some account of the author's life, and special work in relation to the Alpine flora.

Mathematical Society, Thursday, May 9.—Major P. A. Macmahon, R.A., F.R.S., President, in the chair.—Dr. Hobson, F.R.S., made a communication on the most general solution of given degree of Laplace's equation.—Prof. M. J. M. Hill, F.R.S., read two short notes: (1) a property of a skew determinant; (2) on the geometrical meaning of a form of the orthogonal transformation.—Prof. Greenhill, F.R.S., and Mr. T. I. Dewar gave an account of results relating to the spherical catenary. The investigations given in NATURE, p. 262, January 10, 1895, when the parameter of the associated elliptic integral of the third kind is of the form $4\omega_3/\mu$, where ω_3 is the imaginary period and μ is an integer, worked out in detail for $\mu = 3, 4, 5$, and 8, have been extended by Mr. Dewar to the cases of $\mu = 6, 7, 9, 10$, and 12.

In particular, when $\mu = 10$, the catenary is given by an equation of the same form as for $\mu = 5$,

$$(1 - z^2)^{\frac{5}{2}} e^{5\chi i} = Hz^5 + H_1 z^4 + H_2 z^3 + H_3 z^2 + H_4 z + H_5 + i(Lz^3 + L_1 z^2 + L_2 z + L_3)\sqrt{Z},$$

where

$$Z = (1 - z^2)(z - h)^2 - A^2,$$

and

$$\chi = \psi - p\int Z^{-\frac{1}{2}} dz;$$

and it was found that p could be made to vanish, so that the catenary becomes a closed algebraical curve on the sphere, by taking

$$h = \frac{1}{2}\sqrt{\frac{17}{3}},\ A = -\frac{1}{10}\sqrt{\frac{5}{3}},\ L = -\frac{5}{6}\sqrt{\frac{5}{3}},$$

$$L_1 = -\frac{5}{36}\sqrt{85},\ L_2 = \frac{35}{72}\sqrt{\frac{5}{3}},\ L_3 = \frac{13}{144}\sqrt{85};$$

$$H = \frac{1}{6}\sqrt{\frac{17}{3}},\ H_1 = 0,\ H_2 = -\frac{5}{12}\sqrt{\frac{17}{3}},\ H_3 = -\frac{25}{108},$$

$$H_4 = \frac{65}{288}\sqrt{\frac{17}{3}},\ H_5 = \frac{25}{144}.$$

A model was exhibited of this spherical catenary, formed by a chain wrapped on a terrestrial globe; and so far this appears to be the only real algebraical case, for which it is possible for p to vanish.—Mr. G. Heppel exhibited a set of Napier's Bones, of date 1746, and explained how they were used in calculations, referring for a further description of them to the *English Cyclopædia*.—The following papers, in the absence of their authors, were taken as read:—On those orthogonal substitutions that can be generated by the repetition of an infinitesimal orthogonal substitution, by Dr. H. Taber.—Notes on the theory of groups of finite order (continuation), by Prof. W. Burnside, F.R.S.—Applications of trigraphy, by Mr. J. W. Russell: and the reciprocators of two conics, by Messrs. J. W. Russell and A. E. Jolliffe.

Zoological Society, May 7.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—A letter was read from Dr. F. A. Jentink, concerning a monkey lately described as *Cercocebus aterrimus*, of which the type had lately been acquired by the Leyden Museum. Dr. Jentink considered this monkey to be the same as *Cercocebus albigena*, Gray.—Mr. J. H. Gurney exhibited and made remarks on a rare kingfisher (*Alcedo beavani*) obtained in Ceylon by Mr. A. L. Butler.—Mr. G. F. Scott Elliot made some remarks on the fauna of Mount Ruwenzori, in British Central Africa. Mr. Scott Elliot stated that elephants occur in great numbers on the east side of Ruwenzori. There were also many still living and vast stores of ivory in the Congo Free-State, just beyond the south-west corner of the English sphere of influence. He pointed out the presence of the hippopotamus in the Albert-Edward Nyanza, and its extraordinary abundance in the Kagera River. The rhinoceros was found frequently in the country of Karagwe, usually near the marshy lakes leading to the Kagera.—On the alluvial plains about the east of Ruwenzori, Jackson's hartebeest (*Bubalis jacksoni*), the kob (*Cobus kob*), and another waterbuck (perhaps of a new species) were common. No buffaloes were seen. A bushbuck also occurred on Ruwenzori from 7000 to 8000 feet. Of monkeys, Mr. Scott Elliot had noticed the presence of a black and white *Colobus*, which he could not identify, and of at least two other species, probably a *Cercopithecus* and a baboon. Some small mice brought home had not yet been identified. Leopards were numerous, and lions were also common on the lower grounds. Two species of sunbird were brought back, one of which ascends to 11,000 feet on Ruwenzori. Mr. Scott Elliot concluded by remarking that the general idea of distribution gathered from the flora seemed to confirm such data as he could gather from the fauna of the country which he traversed during his journey.—Mr. F. E. Beddard, F.R.S., and Mr. P. Chalmers Mitchell made a communication on the structure of the heart in the alligator, as observed in specimens that had died in the Society's menagerie.—Mr. Chalmers Mitchell described the anatomy of the crested screamer (*Chauna chavaria*), pointing out some resemblances between the alimentary canal of that bird and the ostrich, and giving a detailed comparison of the structures of *Chauna chavaria* and *Palamedea cornuta*.—A communication was read from Dr. Percy Rendall, containing field-notes on the antelopes of the Transvaal.—Dr. Mivart, F.R.S., read a paper on the skeleton of *Lorius flavopalliatus* as compared with that of *Psittacus erithacus*.

Geological Society, May 8.—Dr. Henry Woodward, F.R.S., President, in the chair.—The Stirling dolerite, by Horace W. Monckton. The rock described in the paper forms a mass of about eight miles in length, with an average width of about a mile; it is intruded into the lower part of the carboniferous limestone series. There is little doubt that the Abbey Craig rock, north of the Forth, is connected with the Stirling rock; and there is reason to think that the igneous rocks of Cowden Hill and of the hills around Kilsyth are outlying portions of the Stirling rock, being connected with it underground. All these patches, as well as the main mass, are for the most part composed of a more or less coarse-grained dolerite, the marginal part always becoming finer-grained, whilst the actual edge has apparently been a tachylyte now devitrified. The author gave the results of his macroscopic and microscopic examination of the rocks from various parts of the mass.—Notes on some railway cuttings near Keswick, by J. Postlethwaite. Several cuttings have recently been made on the Cockermouth, Keswick, and Penrith Railway, chiefly through drift, though some occur in the Skiddaw slates, and in one case a diabase dyke (much decomposed) was met with. The author described the drifts as blue clay beneath, and brown clay above, and considered that these two clays were produced during two separate periods of glaciation, with no long interval between. In some places near Keswick water-borne gravel may be seen surmounted by blue clay; this gravel was considered by the author to be of fluviatile origin.—The shelly clays and gravels of Aberdeenshire considered

in relation to the question of submergence, by Dugald Bell. The drifts of this region have been described by Mr. Jamieson, and also in the publications of the Geological Survey. The two authorities agree that the lower (grey) boulder clay of the district was produced by a local glaciation. The geological surveyors, however, maintain that the intervening sands and gravels with marine shells were produced during a submergence of 500 feet or upwards, whilst the upper (red) boulder clay was formed by an ice-sheet from the south. Mr. Jamieson, on the other hand, assigns a purely glacial origin to the middle sands and gravels, and considers that the red clay (which contains a few fragments of marine shells) indicates a submergence. The author discussed these views, and maintained that submergence is not proved in the case of either middle gravels or red clay, but that the former are, as Mr. Jamieson maintained, truly glacial, whilst he advocated the existence of extra-morainic lakes to explain the latter.

PARIS.

Academy of Sciences, May 13.—M. Marey in the chair.—On the cœlostat, a mirror apparatus giving an image of the sky which remains fixed with regard to the earth, by M. G. Lippmann. A plane mirror is mounted on an axis resting on fixed bearings. The mirror and its axis are parallel to the polar axis. A motor turns the system at a uniform speed once round in forty-eight sidereal hours, in the same direction as that of the celestial sphere. The author gives a proof that this mirror fulfils the necessary conditions, and points out wherein it differs from the ordinary siderostat. He shows how the siderostat can be used to demonstrate the principle of the cœlostat, and how the latter instrument can be employed in place of an equatorial. Thermochemical relations between the isomeric forms of ordinary glucose, by M. Berthelot. Three forms of glucose are distinguished: α, the ordinary form, for which $\alpha_D = +106^\circ$; β, produced by transformation of α at 100°, giving $\alpha_D = +52^\circ.5$; and γ, formed from α at 110°, having $\alpha_D = +22^\circ.5$. These rotations are observed immediately on solution; left for some time all are converted into the β form in solution. The change of α into β glucose absorbs 1·55 Cal., the corresponding change of γ into β glucose absorbs 0·67 Cal., in the anhydrous state.—On an automatic registering measuring machine for the comparison of end measures, by M. L. Hartmann.—Researches on the hatching of "l'œuf des sexués" of the vine Phylloxera, by M. L. J. Leroux.—The works printed in the correspondence are: A necrological notice on Ernest Mallard, by M. A. de Lapparent. Petroleum, asphalt, and bitumen, from the geological point of view, by M. A. Jaccard. Invasions of locusts in Algeria, by M. J. Künckel d'Herculais.—Demonstration of Tchébychef's theorem, by M. André Markoff.—On the equivalence of six different forms of expression of the quadratures of algebraical differentials reducible to elliptic integrals, by M. F. de Salvert.—On the integration of the system of differential equations, by M. A. J. Stodolkievitz.—On a new method for the production of fringes with great differences of phase, by M. Gouy. A theoretical paper.—On the electromagnetic theory of the absorption of light in crystals, by M. Bernard Brunhes.—Anomalous rotatory dispersion of absorbent bodies, by M. A. Cotton.—General solution of Maxwell's equations for a homogeneous and isotropic absorbent medium, by M. Birkeland.—On argon and helium. An extract from a letter by Prof. Ramsay to M. Berthelot. An account is given of a sample of gas obtained from a meteoric iron from Augusta County, Virginia, U.S.A. After sparking with oxygen and over caustic soda, the residual gas gave spectroscopic evidence of the presence of argon and helium. Only the lines of argon and helium were observed. This evidence is taken as proof that argon exists in extra-terrestrial bodies, though it has not been noticed in the sun. Helium is found in most of the rare earth minerals examined by Prof. Ramsay.—On the definite combination in copper-aluminium alloys, by M. H. Le Chatelier. The author corrects his previous announcement of the alloy AlCu. The substance had been more profoundly altered by the reagents used than was at the time suspected.—Estimation of sulphur in cast-irons, steels, and irons, by M. Louis Campredon.—Researches on mercurous chloride, bromide, iodide, and oxide, by M. Raoul Varet. A thermochemical paper giving details concerning the heats of formation of these salts.—On the molecular origin of the absorption bands of cobalt and chromium salts, by M. A. Etard. The conclusions are drawn: (1) That chromium salts and the red cobalt salts have fine spectroscopic bands, just as is the case with the rare earth and uranium salts. (2) That these are spectra of molecules like the spectra given by organic substances of the chlorophyll type. (3) The hypothesis that each band of the spectrum of a rare earth corresponds to an element is not necessarily true, according to the evidence of cobalt. (4) The bands may be displaced or disappear for one and the same element according to the nature of the molecules in solution or of the compound observed.—On the molecular modifications of glucose, by M. C. Tanret.—On the use of carbon tetrachloride as a means of separating methylene from ethyl alcohol, by M. Maxime Cari-Mantrand.—On a brown pigment in the elytra of *Curculio cupreus*, by M. A. B. Griffiths.—On the aeration of the soil in the Paris promenades and plantations, by M. Louis Mangin.—On the existence of numerous crystals of orthoclase felspar in the chalk of the Paris basin; proofs of their genesis *in situ*, by M. L. Cayeux.—On gypsum from the neighbourhood of Serres (Hautes-Alpes) and Nyons (Drôme), by M. Victor Paquier.—On the miocene near Bourgoin and Tour-du-Pin, by M. Henri Douxami.—On the presence of *Ostrea (Exogyra) virgula* in the upper Jurassic of the Alpes Maritimes, by M. Adrien Guébhard.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—The Study of "Primitive" Man: E. Clodd (Newnes).—Catalogue of the Fishes in the British Museum, 2nd edition, Vol. 1 (London).—Year-Book of the Scientific and Learned Societies of Great Britain and Ireland, 12th annual issue (Griffin).—L'Industrie Chimique: A. Haller (Paris, Baillière).—My Climbs in the Alps and Caucasus: A. F. Mummery (Unwin).—Transmissions par Cables Métalliques: H. Léauté and A. Bérard (Paris, Gauthier-Villars).—Lessons in Elementary Physics: Prof. J. B. Stewart, new edition (Macmillan).—Agriculture, Practical and Scientific: Prof. J. Muir (Macmillan).—A Monograph of the Order of Oligochæta: F. E. Beddard (Oxford, Clarendon Press).—Fingerprint Directories: Dr. F. Galton (Macmillan).—First Principles of Astronomy: Prof. S. Cooke, 5th edition (Bell).—First Principles of Chemistry: Prof. S. Cooke, 6th edition (Bell).

Cooke, 3rd edition (Bell).—Report of the Departmental Committee upon Merionethshire State Mines (Eyre and Spottiswoode).

SERIALS.—Journal of the Franklin Institute, May (Philadelphia).—Royal Natural History, Part 19 (Warne).—Aus dem Archiv der Deutschen Seewarte, xvii. Jahrg. 1894 (Hamburg).

CONTENTS.

THURSDAY, MAY 30, 1895.

THE SPIRIT OF COOKERY.

The Spirit of Cookery, a Popular Treatise on the History, Science, Practice, and Ethical and Medical Import of Culinary Art. By J. L. W. Thudichum, M.D., F.R.C.P.Lond. (London: Baillière, Tindall, and Cox; Frederick Warne and Co., 1895.)

THE scientific branch of culinary literature has just received in Dr. Thudichum's book an addition which cannot fail to attract the attention of those who give to the selection and preparation of food the consideration that the subject undoubtedly deserves. Of works which come under the denomination of kitchen text-books we have had of late years more than enough perhaps, but treatises on the culinary art from an academical and philosophical point of view have been few. "I could write," said Dr. Johnson, "a better book about cookery than has ever yet been written: it should be a book upon philosophical principles. Pharmacy is now made much more simple. Cookery may be so too. A prescription which is now compounded of five ingredients had formerly fifty in it. So in cookery. If the nature of the ingredients is well known, much fewer will do. Then, as you cannot make bad meat good, I would tell what is the best butcher's meat, the best beef, the best pieces; how to choose young fowls; the proper seasons of different vegetables; and then how to roast, and boil, and compound." The author of "The Spirit of Cookery" has evidently been guided by a similar recognition of the requirements of the case; and seeing that he is a member of a scientific profession which may be said to endow with special advantages those of the cloth who turn their attention to the study of food-stuffs and their treatment, it may be taken for granted that he has executed his task with competence and ability. His object has been "to produce such a system of general rules as will enable those who thoroughly master them to perform the principal culinary operations without reference to the frequently unintelligible records of the details of mere empiricism. These rules," continues he, "are based in the first place upon unimpeachable scientific data or fundamental truths which admit of no circumvention or compromise, and have to be obeyed under pain of certain failure. This obedience has at once its ample reward in clearing the subject of a mass of errors and delusions which disfigure it as a science, and impair its utility, and in placing into the hands of operators the means of attaining their object with certainty and elegance."

Strictly speaking, "The Spirit of Cookery" is a compendium of very useful information gathered, for the most part, from trustworthy sources; its theories are, generally speaking, sound, its principles excellent, and its rules good; but it can scarcely be called a practical work from an executive point of view, for the author rarely allows his descriptions of a process or a dish to go further than a mere sketch. Each branch of the art is nevertheless dealt with, and the principal methods of cooking, if not absolutely worked out in detail, are at all events carefully analysed.

After a glance at the objects of cookery, its literature in the past and present, the requirements of the kitchen, and the processes which appertain thereto, Dr. Thudichum comes to the subject of soup-making. That this is haustively treated, may be gathered from the fact ha more than one hundred pages are devoted to it. The salient feature of this discussion is an exposition of wha the author calls "the complete fallacy of the proposition that bones can either make, or help to make, any liquid that can have any value in cookery." This argument new, or rather let us call it a revival of an old controversy which has been forgotten. That a scientific writer as earnest and experienced as Sir Henry Thompson should have acknowledged, comparatively recently, the value of bones in cookery, in his work "Food and Feeding," would in itself justify our questioning Dr. Thudichum's rather peremptory dictum on this point. Speaking, however from absolutely practical experience to the contrary, we are forced to deny the accuracy of the contention. As a matter of fact, we have been in the constant habit of producing fragrant and savoury broths from the bones poultry and game, both cooked and uncooked, which we have found very valuable in sauces; while in soup-making our working has proved that after six hours cooking on the lines of the *pot-au-feu*, a very perceptible gelatinous element is produced from the bones, which contributes to the quality of the stock. In all circumstances it is of course essential that the bones be broken as small as possible and in the case of those of poultry and game that they be pounded roughly in the mortar. The latest method, viz. that of setting the bones of meat and carcases of poultry intended for the stock-pot to be browned in the oven before addition, is an undoubted improvement, to which the author of "The Spirit of Cookery" would not object perhaps, the addition being made after the first stage of the broth-making, *i.e.* after the liquid (containing the meat alone) has been permitted to come to boiling point for the first time, simmering being conducted afterwards for the allotted period.

Touching the alleged costliness of extracting gelatine from bones, we think that Dr. Thudichum has lost sight of the fact that, inasmuch as kitchen fires are always burning, space can generally be found on the hot-plate for a vessel containing bones where it can simmer without any additional expense in the matter of fuel. We have found that in this way, with the aid of a few vegetables and herbs, very useful broths can be made for the moistening of stews, *purées*, &c., while it is well known that at Aldershot good wholesome pea and lentil soups are made on a bone-stock basis, which form an addition to the soldier's dietary that is much appreciated, and for which no better medium, considering the limited resources of the military kitchen, could be concocted.

We confess that we are surprised at Dr. Thudichum's apparent indifference to vegetables as a factor in the production of a good *bouillon*, for constant practice has satisfied us that all its fragrance and a large share of its pleasant flavour come to the *pot-au-feu* or soup from a very careful proportioning of the vegetables to the meat by weight. In a case of this kind it is idle to speak of "an onion" or "a carrot." We also wonder that he should mention the now obsolete method of clarifying broths with whites of egg and lemon-juice. The object is now attained by raw beef reduced to a pulp, mixed with both the yolk

and white of egg, by which the loss of flavour by the old process has been overcome.

In regard to the author's condemnation of the statement that "the French cook makes excellent and nutritious soup out of materials which the English housewife throws away as useless, while her *pot-au-feu* is composed of stray scraps carefully husbanded, which cost her nothing, but which when skilfully combined constitute a useful and inexpensive food," we would observe that the use of the word *pot-au-feu* is obviously a mistake, but that had *marmite* been substituted there would have been no cause for objection. What says Sir Henry Thompson? "This the *pot-au-feu* is a different thing from the common 'stock-pot' of the French peasant, so frequently termed a *pot-au-feu* and confounded with it. The primary object of the 'stock-pot' is to make a decoction for soup—of animal food if possible—and every morsel of flesh, poultry, trimmings from joints, bones well bruised, &c., which are available for the purpose are reserved for it." This turning to account of scraps is, to our thinking, by no means a "delusion," but a thing that should be encouraged in every economically conducted kitchen. In nearly every other respect we are able to concur with Dr. Thudichum. He is undoubtedly right in pronouncing against the so-called clear soups of restaurants and hotels, in denouncing the free use of wine to smother defects, and the heedless use of cream and butter in *potages liés*, *bisques*, and *purées*.

Turning to his precepts concerning processes, we also find much that we can accept as excellent. Here and there are points, of course, in regard to which the best authorities differ. We would never put fresh meat or poultry, when either has to be cooked for the table by boiling, into *cold* broth or water, having found the method advocated by Sir Henry Thompson better than any other, viz. to immerse the joint or bird in a boiling medium to solidify or coagulate the albumen which pervades the outer layer of meat, and after five or six minutes at that temperature to reduce the heat beneath the vessel to simmering point, never exceeding 180 F. We apply the same principle to the preparation of fish with equally satisfactory results, having proved the accuracy of Sir Henry's axiom that boiling fish in the ordinary manner is of all systems the most wasteful and unsatisfactory. There can be no doubt, though it is contrary to Dr. Thudichum's theory, that the greatest benefit is to be derived from broth made from fish-bones and "cuttings" of white fish, assisted by herbs and vegetables. This we employ as a moistening in our method of fish-poaching, and consider it superior to *court bouillon* with its excessive amount of wine, which Dr. Thudichum very properly condemns.

There is another point on which the doctor's advice is open to question. We refer to his definition of braising as a species of "roasting." Surely this is contrary to the teaching of the best authors. "Braiser la viande," says Dubois, "c'est la cuire à l'étuvée dans un bon fonds de façon à l'atteindre complètement, en lui conservant ses sucs nutritifs." How can a piece of meat be said to be "roasted" when it is moistened in the *braisière* with *bouillon* "*à hauteur*"? The fact is there are varieties of braising. The French cook adopts one method, for instance, for white, and another for brown meats, and, as we read in "Food and Feeding," these vary in treatment. In all the predominating feature is stewing, though the part of the meat exposed by the gradual reduction of the moistening broth may be browned by heat transmitted downwards from hot cinders on the lid of the vessel. The meat is really part stewed, part steamed, and superficially toasted. Dr. Thudichum says nothing of the amount of moistening *mirepoix* necessary for braising, the preliminary browning of the meat, the *couche de racines et oignons émincés* on which it should be placed, the reduction of the first partial moistening, and then the final filling up level with the top of the meat. Without these instructions, how is the student to have placed in his hands "the means of attaining his object with certainty and elegance?"

But the few points to which we have taken exception are of no great consequence in a work which covers as much ground as "The Spirit of Cookery." Some of them might perhaps have been passed over as appertaining to practical work, which Dr. Thudichum may not have intended to explain minutely. There is, as we have said, a great quantity of information which is beyond criticism, plenty of advice which is full of common sense, and a painstaking classification of the principal sections of the art which cannot but be useful to students of cookery. The scientific principles, by which all intelligent work should be guided, are very clearly laid down. The notes on the preparation of food for the sick-room and the camp are excellent, and all who recognise the necessity of encouraging cookery for the palate rather than for the eye will concur in Dr. Thudichum's observations regarding the vulgar folly of over-ornamentation.

WEATHER OBSERVATION AND PREDICTIONS.

Meteorology, Weather, and Methods of Forecasting, Description of Meteorological Instruments, and River Flood Predictions in the United States. By Thomas Russell, U.S. Assistant-Engineer. (New York: Macmillan and Co., 1895.)

Results of Rain, River, and Evaporation Observations, made in New South Wales during 1893. By H. C. Russell, B.A., C.M.G., F.R.S. (Sydney: C. Potter, 1894.)

THE first of these two books has for its aim the instruction of those who are interested in the weather, and wish to make forecasts on scientific lines, or to understand the principles which underlie the predictions issued by responsible authorities. The expression "scientific lines" is, perhaps, not justified. Experience plays, probably, as large a part as science. The knowledge of the character of the weather that has followed certain definite atmospheric conditions in former cases, is to some extent a guide as to what will happen when those conditions again present themselves, and possibly as true a guide as any result based on the wider knowledge of the general circulation of the atmosphere. Especially has the particular study of the direction and rate of motion of cyclonic areas, with their attendant phenomena of rain, and change of temperature permitted a greater amount of security in weather predictions for

short intervals of time. But this great certainty is based upon experience and observation, rather than upon purely thermo-dynamic principles.

The evidence of decisive progress in forecasting is wanting. Nor does the author hold out a very sanguine hope of the possibility of issuing in the immediate future successful weather forecasts over large districts from a central bureau. There are not more than six to twelve occasions, in the course of a year, for any part of the country, he tells us in the preface, "where successful predictions can be made, and for some places successful predictions are never possible." "Successful continuous predictions for every day are not possible." This is the opinion of one who apparently has ample means of forming an adequate judgment. It is the outcome in a country where the opportunities of framing forecasts are many and favourable. The service is well supplied both with funds and officers, the vast telegraphic system of the country is at the disposal of the Weather Bureau, the area over which the data are collected is extensive enough to enable the whole development of a storm to be watched and reported, while the favourable situation of Washington, in the extreme east of the continent, is a point not to be omitted. Yet after years of trial, the opinion of one who apparently has official connection with the system, or is at least well supplied with information from the Bureau, is, that the complete solution of the problem is not only impossible, but is only practically effective on the average less than once a month. If this be the result under favourable conditions, what, it may be asked, is the system worth in England, where our insular position cuts off the supply of any information from the West, the direction in which our principal storms approach, and the intelligence from the East has to be supplied by the courtesy of many nationalities, and more or less hampered by different telegraphic systems.

To return to the book, however, which in some respects is a little disappointing. There is an occasional appearance of hurry in the compilation of the work, which has sometimes prevented the author expressing himself with sufficient clearness, and with the reservations which are sometimes necessary. For instance, we are told, on p. 3, that there is less oxygen in the air when the wind is from the south, than when the direction is north. This may be true for the district in which the author lives, but as there is no indication where this particular locality is situated, and the preface is not even dated, we are left to infer that the remark applies to the earth generally, which can scarcely be correct. Again, on p. 184, in the description of secondary low pressures, occurs this sentence. "In Fig. 29, thunderstorms are very apt to occur with secondary low pressures." This statement is certainly a puzzle. On p. 190 we are referred to a map on the adjoining page. There is no map there, although this map is referred to in the list of illustrations. Readers will, however, find it at the end of the book. Sometimes, too, facts which are easily verified are not quoted with accuracy. On p. 5, the dates of the earth's perihelion and aphelion passage are given as December 23 and June 21 respectively. The area of the Caspian Sea is given on p. 101 as over 200,000 square miles, and on p. 201 as 180,000 square miles. But these and many other small blemishes can be removed in a future edition.

We are more concerned to look at the work as a whole, and to consider what special service is it likely to render among the host of meteorological treatises that are continually appearing on one or other side of the Atlantic We have, of course, the ordinary chapter on meteorological instruments ; we have the cloud classification ; we have the description of the rain and hail and snow, that too frequently make life unpleasant ; together with all the winds that blow, or are likely to blow. And the oft-told tale, it must be confessed, is repeated in rather a jerky manner, partaking of something of the manner of a dictionary, wherein one is treated to a collection of definitions. The last chapters of the book are undoubtedly the best. There the author has something to tell us of processes not generally described in books like the present. To the charm of novelty is added the advantage that we feel we are listening to a practical expert, who can tell us all that is worth knowing about river-floods and overflows.

We come now to the second volume under notice. Fortunately in this country we are not frequently troubled by the overflow of rivers and the consequent destruction of property on the banks, and therefore the subject with us receives scant attention. Probably for this reason the report of the Meteorological Council is silent on such matters, though at times like last autumn, the inhabitants of Eton, Oxford, and the Thames Valley would have been gratified by a timely warning. It may have been that warnings were given, but from the absence from the Report of any mention of machinery adapted to this end, one would infer that this is an inquiry the Council do not consider worthy of their attention. Far different is it with the Astronomer at Sydney, whose latest report is mentioned at the head of this notice. There the subject is forced on the attention of scientific men : and on the unscientific, too, if he happen to live in a district where, as Mr. Russell reports, the rise of a river was so rapid that in less than two hours a part of a town was covered to a depth of three or four feet, and the people were glad to escape with their lives at the sacrifice of their property. Mr. Russell has great difficulties to contend with. He has not only the small equipment peculiar to a comparatively new colony, imperfect data, and the slow accumulation of facts, but the first warning of the rise of a flood may occur in uninhabited or thinly populated districts, with which communication is slow and uncertain. The American Bureau has not to struggle against these disadvantages, but the problem depends upon so many variable quantities that the complete solution is practically impossible.

The author of the treatise on meteorology lays it down that very little connection can be traced between meteorological laws and river floods, except perhaps in cases where the quantity of water is dependent upon the melting of the snow. In temperate zones, floods occur without any very noticeable great rainfalls. Intermittent rain may cause a river to rise very slowly, and almost imperceptibly, till it be bank-full, when a moderate rain makes the river overflow. Neither is there any decided connection between the river slopes and velocity, so that

the velocity of the flow cannot be computed from a knowledge of the slope. The character of the ground over which the rain falls—that is, the degree of permeability—is a fruitful source of uncertainty in predicting the probable rise. There are many other obvious sources of error, so that no one can be surprised to learn that the theoretical determination of a river rise cannot be treated as a problem in hydraulics. Without a system of gauges along the river, predictions are scarcely possible. With their employment, the problem becomes more or less one of practice and experience. This remark may be illustrated by showing how the rise of the river may be predicted for Pittsburg, a place where the observations of rainfall simply, are of little use in foretelling with accuracy the height to which the river will rise. The rise is predicted from observations of the rise at stations above the town, or on tributaries. Gauges are maintained at Oil City, Brookville, Confluence, Rowlesburg, Weston, and Johnstown. These towns lie both north and south of Pittsburg, and the greatest separation may amount to two hundred miles. The height of the river and its tributaries at each of these places not only exercises a different effect at Pittsburg, presumed to be proportional to the square root of the area drained by the rivers at each station, but the height of the river at Pittsburg itself has also to be taken into the account. The higher the stage at Pittsburg, the less will the river be affected by the same rise at the upper stations. "It is assumed that the rise multiplied by the mean stage during the rise is comparable throughout different stages for Pittsburg." The factors deduced from the area drained vary from 2·1 for Oil City to 0·1 at Weston, and the observed rise between two consecutive days multiplied by these factors can be easily tabulated to exhibit the expected rise at Pittsburg. Mr. Russell has worked out some examples to show the successful application of this method. On February 16, 1891, the calculated height of the stage was 31·3 feet; the observed, 32 feet. On February 6, 1893, the calculated height was 23 feet; the observed, 23·1. It does not appear how far these examples are illustrative of the success attending the general application, but the system seems to leave nothing to be desired. The author takes us regularly down the Ohio River to Cincinnati, Louisville, and Cairo, the junction with the Mississippi, illustrating the modifications which varying conditions may render necessary. The Missouri and the Mississippi also receive their share of attention, and the book forms a very practical guide for those interested in such matters. The value of the whole process rests on the provision of a sufficient number of well placed gauges, and a long series of observations, from which may be learnt the probable behaviour of the river under all circumstances. It is in this direction, apparently, that Mr. Russell, of Sydney, finds his opportunity, and the great mass of facts that he is collecting will be of the greatest use as the colony becomes more thickly peopled. We do not understand that he has yet arrived at the stage of predicting with accuracy and confidence the vertical rise and fall of the rivers over which he watches. His part, if apparently less interesting, is not less useful; and he is to be congratulated on the spread of his system of observations and his successful overthrow of many old theories.

AN ALBUM OF CLASSICAL ANTIQUITIES.

Atlas of Classical Antiquities. By Th. Schreiber. Edited for English use, by Prof. W. C. Anderson, of Firth College, Sheffield. (London: Macmillan, 1895.)

THIS work should hardly be called an Atlas, since, though it contains a vast amount of matter, the disjointed arrangement is by no means that of an Atlas. The abundance of illustrations, however, makes the book exceedingly valuable to the student.

But although there may be, and is the *facundia*, the *lucidus ordo* is frequently wanting. Still, by the help of the excellent trilinqual index, supplied by the English editor, this defect is much remedied.

The book should also be judged by reference to what it aims to be. If considered as a work addressed to artists or specialists, great deficiencies in the technical execution of the plates would have to be complained of; but it should be looked at mainly as a series of rough sketches of ancient life as revealed to us through art, for the instruction of students in literature and commencing archæologists, or as a general book of reference. The above remarks refer entirely to Herr Schreiber's plates; nothing but praise should be accorded to Prof. Anderson as translator and expositor. The aim of the work is sufficiently stated in the preface.

"There springs up a desire for facts—facts as to the life of the ancients, their laws and their customs, their beliefs and their cults. Because no fact is despicable from the point of view of science, we further look into their daily life—the fashion of their dress and their houses, the arrangements of the theatre and the market-place. And since no source of facts can be so perfectly trustworthy as the works of contemporary art, those works gain an interest, arising not merely from their own beauty, but as the crystallisation of the visible life of the people, a mirror of their thought preserved to us like many actual Greek mirrors in the graves of the dead."

The series of plates begins with theatres and acting; and with respect, at least, to Roman or Romanised Greek theatres, they are very fully illustrated, both as regards the fabric and the actor, but there is a remarkable absence of the characteristics of the Greek theatre as distinguished from the Roman, which have been much under discussion of late years. Plate iii., Fig. 3, however, introduces a representation of the raised stage or λογεῖον, which, if the date ascribed to it in the text be accurate, bears strongly against the theory that all the action took place on the level of the orchestra until the raised *pulpitum* was introduced by the Romans. In Plate ix. we see that some of our modern building appliances have been in continuous use since classical times. In Plate x., Fig. 3, after Durm, the contrivance of the wooden blocks and pin in the joints of the columns of the Parthenon is not accurately shown, and it is therefore not surprising that in the text a difficulty is hinted at. The smaller shallow circle was not provided for the purpose of receiving a wooden cylinder to turn in. This was the function of the smaller pin or cylinder of hard wood, which was centred in the square wooden blocks which were fixed in each bed of the joint. The shallow circle in the stone was provided to receive the detritus caused by rubbing the stones together. In the same plate ornament is shown on the echinus of the Doric capital.

Decoration of this member is, to say the least, extremely doubtful. Two valuable plates follow of Olympia, in plan and perspective. The restored view of the Acropolis of Athens, however, is hardly so successful. The drawing is coarse, and it gives a very inadequate idea of the way in which the Acropolis dominates the valley to the south of it. In Plate xiv., Figs. 1 and 2 (the latter from a vase) are interesting from their connection with the Eleusinian mysteries. As many of the illustrations are necessarily taken from vases, it would have been serviceable for beginners if some representation with a short description of different kinds of vases, such as the cylix, the lecythus, &c., had been given. Plate xv. shows that votive offerings of models of diseased limbs and other bodily members, suspended at the altars of favourite saints, had their origin in classical times. In its reference to Fig. 2, of Plate xviii., the text gives a valuable reference to the recent discoveries at the Pantheon, which were lately made under the direction of the French architect, M. Chedanne.

Plate xix., Fig. 15, is interesting as showing that the division of the heavens into different *houses* of the mediæval astrologers had its origin in classical augury. Plates xx. to xxiv. are devoted to athletics. In Plate xxii. are illustrations of the method of throwing javelins by means of the *amentum*, a kind of sling attached to the shaft. Some are shown as being thrown overhand, and others underhand, and a curious method by which aid was given to jumping by means of weights held in the hands. Plates xxvii. to xxxiii. are devoted to games and arena combats. Fig. 4 in the first of these plates, from a wall-painting from Pompeii, is an interesting illustration, described thus in the text: "This painting is unique as a contemporary picture of an historical event. Tacitus ("Annals," xiv. 17) mentions a riot between the people of Nuceria and Pompeii which arose out of a gladiatorial show given by Livineius Regulus. It began with mutual taunts, and then stones were thrown and weapons used. The Pompeians were naturally the stronger party, so that many of the Nucerians were badly wounded, and several slain. As a consequence, Nero stopped the games for ten years. The painting shows the fighting going on in and about the amphitheatre." Fig. 1 in Plate xxxiii., from Brescia, shows that combats with wild beasts were still practised in 530 A.D. in Italy. In Plate xxxiv. we have representations of early Greek warriors and weapons, and also, but of later date, a besieged city from the Nereid tomb in the British Museum, and in Plate xli. a useful diagram showing the arrangement of a Roman camp. In the same and following plates Roman soldiers and their armour are well given, and Greek and other helmets. Young students of Cæsar "de Bello Gallico" will be thankful for the illustrations of the Rhine Bridge in Plate xliv. In Plate xlvi. is the difficult subject of the trireme and its oars. It contains only one original document (Fig. 8), namely, the sculptured relief found near the Erechtheum; the other figures are reconstructions in which the difficulty does not appear to have been grasped. The ancient relief certainly implies oars of different lengths; thus much cannot be controverted, but the only possible means by which the rowers on the different banks could have kept time would have been by an inversely corresponding difference given to the surface of the blades of the oars, which the reconstructions do not show.

Plates xlviiii. to li. are occupied by town gateways and fortifications. Then follow private houses, aqueducts, bridges, baths, and calculating boards. In Plate lxii. ancient sundials, which divided the day from rising to setting sun into twelve hours, irrespective of the difference of their lengths in summer or winter. Then follow various agricultural operations, and in Plate lxvi. a warehouse scene, the weighing silphium, a plant used in medicine, grown in Cyrene; a group of decidedly Egyptian type. Then ovens, Plate lxvii., for baking bread; Plate lxviii., for pottery. From Plates lxix. to lxxvi., various arts and crafts. The triclinium is shown and explained in Plate lxxvii. Then follows jugglery and games. Plate lxxxi. shows bridal scenes, followed by female dresses and costumes. In Plate lxxxvii. is a relief from the arch of Constantine, introducing several details of the Roman forum. Plate lxxxviii. follows with a graphic scene of civic life from a wall-painting of Pompeii. Then school scenes are illustrated with wax tablets and writing materials; there is also a pair of proportional compasses, having much analogy to the instrument in modern use. Plates xcii. A and xciii. tell the "tale of Troy divine," from a relief of the Augustan age, representing the Iliupersis, found near Bovillae; and the work concludes with a very complete series of burial scenes—that is, of interment—for there are no representations of cremation. But notwithstanding this and some other omissions, the hundred crowded plates of this volume, from which we have made only a few extracts, contain a vast store of objects for reference, and they are all very much enhanced in value by the descriptions and notes with which Mr. Anderson has enriched the book.

A DESIDERATUM IN MODERN BOTANICAL LITERATURE.

A Hand-book of Systematic Botany. By Dr. E. Warming, Professor of Botany in the University of Copenhagen. With a Revision of the Fungi, by Dr. G. Knoblauch, Karlsruhe. Translated and edited by M. C. Potter, M.A., F.L.S., Professor of Botany in the University of Durham College of Science, Newcastle-upon-Tyne. (London: Swan Sonnenschein and Co., 1895.)

It is a curious, and not altogether a pleasant reflection, considering the activity which has been displayed by the botanists of this country within recent years, that we should still be largely dependent on foreign sources for our text-books in more than one main division of this particular science. It is doubtless true that the books are sometimes more or less edited, before they are presented to the English student, but still one can hardly help feeling that an entirely home-grown article, if issuing from first-rate hands, would prove a most welcome change.

It is with somewhat mixed feelings, then, that we greet the appearance of Prof. Warming's "Hand-book of Systematic Botany" in its English form. Moreover, we feel a little inclined at the very outset to quarrel with the title of the book before us; a *hand-book* of systematic botany embodying critical morphological discussion, is exactly what is now wanted—something which may be to us what Eichler's celebrated *Blüthendiagramme* was, and

indeed still is, to our German neighbours. But one can hardly allow that the present volume rises above the rank of a text-book, and of these we have plenty with us. Not that it is intended to depreciate the value of Prof. Warming's book; it is chiefly the question whether an increase of this particular kind of book is just now wanted at all, whilst there is no question whatever but that a genuine "hand-book" is very much needed indeed. As far as the work goes it is very good, at least in its manner of dealing with the Angiosperms, but it does not go far enough. Thus the order Cucurbitaceæ, as an example taken at random, is dismissed with something less than four pages, and yet the plants included in this order abound in interesting characters. To treat these and others of a similar nature in a brief dogmatic fashion is to abandon the most interesting side of the subject, to say nothing of the educational opportunities which have been missed. But notwithstanding these features of the work, which, professing as it does to be a hand-book, appear to us to be serious defects, we readily admit that, taken as a whole, the account given of the flowering plants is one of the best existing in the English language. The lower groups of plants are less satisfactorily dealt with. In the Fungi, the general method of arrangement followed is that based on Brefeld's researches, but the difficulties connected with *Eremascus* are not touched upon. It may be doubted whether the student will gain a very clear idea of *Oidia*, which, he is told, must be distinguished from "true chlamydospores." The definition runs thus: "The former (*Oidia*), are more simple, the latter are somewhat more differentiated form of carpophore fundaments, which serve for propagation in the same manner as spores." But exactly wherein the difference really consists we seek in vain to find. A purist might object to the expression "brand"-fungi, which is used instead of the more familiar one of smut-fungi; a practical farmer, in this country at least, would also probably smile at the description given of the method of application of blue vitriol as a preventative of the disease caused by these organisms in cereal crops.

The treatment of the Muscineæ strikes us as far too cursory, especially in regard to the considerable amount of work recently done in connection with these plants. The brief statement of Celakovsky's view as to the homology of the moss sporogonium is only calculated to confuse the mind of a student by introducing purely idealistic notions, and its value without a full explanation is absolutely inappreciable. The catalogue of "orders" of mosses, given on pp. 196–197, is also particularly depressing.

The treatment of the vascular cryptogams is decidedly weak, and this is the more surprising, considering the activity which has long been displayed in the investigation of this division of plants. The general description of the embryo, given on p. 201, only applies to a few families, and is not by any means true for most of the groups. Again the usual mistake is made as regards the sporangium of Isoetes, which is stated to be divided into "compartments one above another"; the fact, of course, being that it is not divided into "compartments" at all, as an inspection of a tangential section will suffice to show.

It is surprising, in a work issued in 1895, to find the old erroneous description of the germination of the gymnosperm pollen-grain still maintained. We note, however, with satisfaction that a popular mistake (which appears also in the text) is corrected in an editorial note, in which it is rightly stated that Cycads commonly *do* branch in a state of nature.

From what has been said, it will be clear that the treatment of the lower plants is inadequate, and it is to be regretted that Prof. Potter did not see his way to using his editorial discretion more freely. It is, however, easy to find fault with most books; but we have already said that, as regards the latter half of the volume, it is deserving of commendation, and we may add that it is well illustrated, and that, further, it contains, in the form of an appendix by Prof. Potter, a brief account of the chief methods of classification which have been used in arranging the members of the vegetable kingdom.

OUR BOOK SHELF.

The Noxious and Beneficial Insects of the State of Illinois. Eighteenth Report of the State Entomologist. Seventh Report of S. A. Forbes. For the years 1891 and 1892. (Springfield, Ill., U.S.A., 1894.)

THIS report is mainly devoted to insect attacks affecting "Indian corn" (sometimes known with us as "maize," in the U.S.A. shortly as "corn"), and coming from the trustworthy and well-qualified pen of Prof. Forbes, will be of much service in the country of the crop dealt with, and, in points noticed regarding such of these "pests" as are of very similar habits with our own, may be studied here with much advantage.

The "Monograph of Insect Injuries to Indian Corn" extends to 165 pages, dealing with insects of very various kinds, including amongst them what, without entering here on their scientific appellations, may be generally described as ants of various kinds; beetles, including allies of our turnip flea beetle, wireworms, with click beetle parents, and chafers, with their grubs (truly noted as "the immemorial enemies of agriculture on both sides of the Atlantic"); aphides, or plant lice of various kinds, and some other insects.

The information is the result of ten years' investigation of the economic entomology of the Indian corn plant by the official entomologist of Illinois, joined to such additions from published matter as it appeared desirable to embody with his original observations; and in the words of the writer, whilst a portion of the information is such as he hopes will be "intelligible and practically useful to the actual tiller of the soil," he has also incorporated with this, for "the special benefit of the entomologist, more detailed and thorough-going discussions of the insects themselves, and of their life-histories, habits, and injuries, together with descriptions of the species in all stages as yet recognised."

These minute descriptions, especially of the early stages (so important to the economic entomologist, and so difficult, too often, to obtain) in themselves give the work a high value, and in the practical part there is much to be studied with great benefit. To give a single instance—the indifference of wireworms to various kinds of poisons prepared for their consumption on seed placed for their use (p. 49).

The report is greatly to be recommended to the study of economic entomologists, and its value is added to by fifteen well-executed full-page plates of many of the insects referred to, also by an exhaustive index of thirteen pages, so complete and well arranged as in some instances almost to give headings for a life-history of the insect referred to.

F. A. O.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Origin of the Cultivated Cineraria.

REFERRING to records of the history of cultivated Cineraria, I found (1) that considerable sports, or seedlings presenting notable and striking variations, arose in the early days of the "improvement" of the Cineraria; (2) that there is evidence that the improved varieties were of hybrid origin. I concluded, therefore, that Mr. Dyer's statement that our Cinerarias have been derived from *C. cruenta* "by the gradual accumulation of small variations" was misleading in two respects. As we have now had the benefit of a fuller statement of Mr. Dyer's case, I ask leave to explain why it is that I still hold to my original conclusion.

Meanwhile, however, Prof. Weldon, intervening, has offered an apparently sustained criticism of my evidence, which to those no better prepared may have a formidable look.

We will first examine some of Prof. Weldon's minor points. In preface let me say that I do not contend that *no* sports or named varieties have ever been believed to have arisen directly from *cruenta*, or from plants so-called (for, as Willdenow hinted,[1] the name may have been misapplied to hybrids in the past as now); and, indeed, I gave Drummond's words that his *cruenta* "sported freely from seed."

Something was made also of the wise caution which Burbidge gives in his general "Introduction" (p. 118), putting the reader on his guard against specific assertions as to the origin of hybrids. I mention, therefore, that I have received from Mr. Burbidge a letter warmly supporting the opinion given in the body of his book (p. 249) that the Cinerarias are of hybrid origin.

But now for what Prof. Weldon takes to be the real strength of his attack. He says that I omitted passages proving that according to contemporary opinion many of the named varieties cultivated between 1838 and 1842 "were not hybrids," but were "believed to be pure-bred *cruenta*." Upon what grounds this statement has been made, the reader shall now learn, not perhaps without astonishment.

The passage on which he chiefly relies is taken from Mrs. Loudon's article (*Ladies' Mag. of Gard.*, 1842, p. 111), to which I referred for the statement that in the writer's opinion the first important departure in the improvement of the Cineraria was made when Drummond hybridised *cruenta* with *lanata*. She goes on to say that, "since that time, numerous experiments have been made and hybrids raised" from several species. Next, that "some of the most beautiful Cinerarias now in our greenhouses, have been raised by Messrs. Henderson, Pineapple Place, particularly *C. Hendersoni* and the King, both raised from seeds of *C. cruenta*." This is the passage I omitted. Prof. Weldon says that this "passage clearly shows that in the writer's [Mrs. Loudon's] belief, the hybrids produced by Drummond and others, had not given rise to two at least of the named varieties of her time," and that she believed the King and *Hendersonii* to be descended from *cruenta* alone. This Prof. Weldon tells us is certain

Now, were we even bounded by the limit Prof. Weldon has set to his own researches on this question, we might hesitate to assume that whenever it is not expressly declared that a plant is a hybrid, we may be sure that the author thought it was pure-bred. As it happens, however, I can meet the charge with a weapon sturdier than the fine point of "dialectic." The answer is quite simple and curiously complete.

I shall now prove that both the King and *Hendersonii* were well known as hybrids both to Mrs. Loudon and to others. Let me point out:

(1) That the words say that the King and *C. Hendersonii* were raised from *seeds* of *cruenta*: as to the *male* parent, nothing is there said.

(2) That even if the evidence ended here, a discriminating reader might have suspected (what I shall presently prove) that Mrs. Loudon's *particular* statement about the King, *Hendersonii*, &c., is merely meant as an expansion of her previous *general* statement that since Drummond made his beginning numerous hybrids had been raised.

(3) That, were the matter doubtful, other passages in Mrs. Loudon's works prove this to be her meaning. For in *Ladies' Comp. to Flower-Gard.*, 1849 (s. v. Cineraria), she states, "the finest hybrids are *C. Waterhousiana*, *C. Hendersonii*, and the kind called the King." Again, in *Ladies' Flower-Gard.*, *Greenho. Plts.*, 1848, p. 178, speaking of the woolly leaves, &c., of *lanata*, she says, "these peculiarities are found in all the numerous hybrids that have been raised from it. Perhaps the most ornamental of these is the hybrid called the King."[1] Of this, therefore, I presume Mrs. Loudon believed *lanata* to be the father, *cruenta* the mother.

(4) Lastly, that in order to have learnt that the King and *Hendersonii* were "between 1838 and 1842" considered to be hybrids, Prof. Weldon need not have gone far. He tells us he has read the articles on *C. Webberiana* (*Paxt. Mag.*, 1842, p. 125) and on *C. Waterhousiana* (*ibid.*, 1838, p. 219), to which I gave references. Will it then be believed that in the first of these very articles *the King is referred to by name as a notable hybrid*: and that in the second article, "*C. cruenta*, var. *Hendersonia*" is with others named as *one of* "*the hybrids raised and grown by Messrs. Henderson, Pine-apple Place!*"

I do not know if it is wished that I should further refute Prof. Weldon's charge of "want of care in consulting and quoting the authorities." I am not unprepared to do so. I shall be glad to explain why Mrs. Loudon was probably right in substituting the name *tussilaginis* for *tussilagofolia*: to show why *Webberiana*, price 10s. 6d. (*Gard. Chron.*, 1842, p. 665), may be called a striking advance on its contemporaries, price 2s. 6d. (*Gard. Chron.*, 1842, p. 633), together with many other matters not yet treated of in this discussion.

My first objection to Mr. Dyer's statement was taken on the ground that there is historical evidence that sports, or seedlings presenting notable variations, occurred in the early days of the improvement of the Cineraria. To this, after reading his letters with great care, I do not find any specific answer. He tells us that the history as he gave it would be "in accord with general horticultural experience." It obeyed then a rule to the proof of which exceptions are indeed not lacking. He says, further, that to improve a plant the only safe way is by "selecting the minutest trace of change in the required direction," and "by patiently and continuously repeating the operation." Now this would be all very well if we knew nothing about the origin of the Cineraria; but against the evidence that seedlings presenting striking variations did as a fact arise, and against the historical evidence that Cinerarias, much as we know them, did as a fact come into existence within some twelve years, such *à priori* expectation is worth nothing at all.

To my second objection, that there is evidence that the chief start in the improvement of Cinerarias came as the result of hybridisation, Mr. Dyer has given more attention. He proposes to meet it by rejecting the whole of the historical evidence as unsound, and preferring the conjecture to which he says an inspection of the modern plants has led him. The historical evidence is to go because we are told certain horticulturists are ignorant men. I premise that this is not a principle which Darwin, whom Mr. Dyer would claim as his master, would have endorsed.

But before judging, let us try to consider what was the objective evidence on which the gardeners made up their minds that the new Cinerarias were hybrids. I may illustrate this by reference to a seedling now growing in the Cambridge Botanic Garden, to which Mr. Lynch, the curator, kindly called my attention. The case is of special interest in view of Mr Hemsley's objection that it requires skill and care to raise a hybrid in the Compositæ. It was with regret I learnt that this careful writer was not with me in this matter.

This seedling was raised from a seed of our plant of *lanata*, which was received from and is exactly similar to those at Kew.[2]

[1] He says ("Enum. Pl. Berol.," 1809, p. 893) that Cinerarias are grown in gardens under the name *cruenta*, though really very different from it, having flowers almost like those of *lanata*. To these he gave the name *C. hybrida*. Moreover, from Bouché's experiment, we know that the seedlings of this *C. hybrida* were very variable.

[1] So famous a hybrid was the King, that I regret that I did not mention it in my first letter. I did not do so, as I found no coloured plate of it. Mr. John Fraser, of South Woodford, kindly informs me that he remembers it as the best of the woody sorts formerly grown. Its flowers were about the size of a penny, rays white tipped with purple, leaves downy and of a silvery hue on the underside. Its seedlings were unreliable.

[2] There labelled *Héritieri* (of DC.=*lanata*, L'Hér.). I note that though otherwise agreeing exactly with the *lanata* described by L'Her., de Candolle and Webb, the inflorescence of these plants differs, being a loose corymb of some twenty heads, instead of the single flowered peduncle (*rami semper monocephali*, Webb) of the old authors. Whether this variation is known in wild plants, I cannot tell.

In habit and size our seedling is not at all like *lanata*, but might be taken for a poor specimen of the common Cinerarias. In several characters it is intermediate between *lanata* and the latter. The stem is rather woody, less so than in *lanata*, but it is thick like those of garden kinds: petioles like *lanata* in having no auricles: leaves, nevertheless, large like those of garden kinds, the backs very woolly, but largely purplish, as in many cultivated sorts. Now this plant must be either (1) a sport from *lanata* in the direction of the garden forms, or (2) an accidental hybrid between *lanata* and one of the cultivated kinds growing in the same house with it (we have no others). The latter seems more likely—an opinion in which Mr. Lynch fully concurs.

Similarly Bouché (*Wittm. Monats.*, xxii. p. 298, orig. not seen, quoted from Focke, *Pfl. Mischlinge*, 1881, p. 201) says that a hybrid between *C. Webbii* (Schlz. Bipont.) and *cruenta* arose in the Berlin Botanic Garden as the spontaneous product of these species growing side by side.

It was, I think, on evidence like this that the parentage of the older hybrids was conjectured; but that Drummond and Henderson certainly—and possibly others—did make definite efforts to hybridise, cannot on the evidence be doubted. That these efforts went no further than the brushing of pollen of some species upon the flowers of others, I fully believe, and that on such evidence the *precise* parentage cannot be assigned is obvious. Nevertheless distinct seedlings resulted. In a few years, as the writer in *Paxt. Mag.*, 1842, p. 125, says (in an article urging to fresh efforts in crossing), this hybridisation "was the means of creating quite a novel and superior race." There were the new plants: how had they arisen? Those who doubt that these new kinds were hybrids must choose the other horn of the dilemma, and accept them as sports pure and simple.

That the historical records may contain errors, I am fully aware; but if they cannot be accepted in detail, should they be altogether rejected? We might perhaps reserve a doubt whether the King came precisely from pure *cruenta* fertilised by *lanata*; whether *cruenta* var. *lutea* was a hybrid between *cruenta* and *populifolia* (as de Candolle surmises); whether *Waterhousiana* was the offspring of true *cruenta* and true *tussilaginis*; whether Mrs. Loudon's statement that the species used were *cruenta*, *lanata*, *aurita*, *tussilaginis*, and *populifolia*, or Moore's belief that *cruenta* and *tussilaginis*, with perhaps *Héritieri* (= *lanata*), *maderensis* (= *aurita*), and *populifolia* ("Cross and Self-Fert.," p. 335, *note*), or Otto's similar declaration (Regel's *Gartenflora*, 1857, p. 66), or that of the *Jour. d'hort. Gand*, 1846, already given, should each be taken without hesitation as full and complete statements of the whole truth, but that they contain a substance of truth is hardly in question.

Against this Mr. Dyer offers nothing but an opinion derived from an inspection of certain modern plants. He who has confidence in the results of this method must suppose our knowledge of the laws of inheritance to be much more complete than I believe it to be. It is not the method Darwin used. Take a well-ascertained case. Who would know from inspection of the Himalaya rabbit that it came directly from the Silver-greys or Chinchillas? (See *Animals and Pl.*, i. p. 113.) It is unlike them, is of sudden origin, and yet breeds true.[1] To suppose that in cross-bred offspring given characteristics of the parents must be found, is to assume the precise question which in a discussion of organic stability is at issue. Let it be remembered that on the hypothesis of hybrid origin for our Cinerarias it is supposed that they result from several species and varieties, crossed not once only, but many times, in wholly irregular ways. Can it be seriously expected that any special resemblance to a given ancestor should be still traceable?[2]

My position then is this. We heard Mr. Dyer's statement; turning to the literature I found an entirely different account, borne out by copious and on the whole fairly attested evidence, pointing irresistibly to the conclusion that the Cinerarias are [illegible] which hybridise freely, and that our modern forms have [illegible] through such hybrid unions.

[1] [illegible] Mr. [illegible] Royal, [illegible] grower, and to [illegible] several interesting points, and especially for the [illegible] featured [illegible] in his strain. [illegible] introduced some plants of a French strain. After this, [illegible] of the cross between [illegible] the French kinds, [illegible] seeders themselves, [illegible] strongly that they have to be kept in a house [illegible] to the exclusion of everything else.

[2] [illegible] Mr. Dyer [illegible] I have assumed, what I [illegible]

Mr. Dyer has well said that "if you take any statement that Mr. Darwin has put forward, you may feel assured that behind it is a formidable body of carefully considered evidence not likely to be upset." By the courtesy of an opponent I have been directed to a passage in "Cross and Self-Fertilization," 1876, p. 335, where (before describing experiments showing considerable self-sterility in the garden Cineraria) Darwin gives this definition of his material, "*Senecio cruentus* (*greenhouse varieties, commonly called Cinerarias, probably derived from several fruticose or herbaceous species much intercrossed*")." It seems, therefore, that in this matter also Mr. Darwin has, to use Mr. Dyer's words, "squeezed out" of the evidence "all that it would profitably yield."

Here I would fain leave the subject. But perhaps it may be suggested that though Darwin's Cinerarias were probably hybrids, our Cinerarias may not be their descendants. Such a suggestion involves the supposition that in some hidden place there was a thin red line of pure *cruenta* waiting for the moment when it should oust the hybrids. If this be seriously suggested, I shall ask where such a strain was kept, and what steps were taken to preserve its purity. In view of the evidence that chance blendings occur freely, to keep a pure strain would require some care. Until this has been proved, we shall not, I think, be wrong in supposing that each grower worked on the material his predecessors had created, and that our Cinerarias are the lineal descendants of the hybrids raised in the first half of this century.

In the course of this discussion, Mr. Dyer has treated me to some hard words, which I do not particularly resent. Whether I have deserved them is not, perhaps, for me to judge. But I will ask Mr. Dyer to point out when, on being asked for the facts upon which I have based a view, I have replied that that was a "matter for future collection." The facts I have been able to collect may be few, but by a study of the writings of my antagonists, I have not been able to add materially to their number.[1]

W. Bateson.

St. John's College, Cambridge, May 26.

It has been pointed out to me that my remarks on Mr. Bateson's account of the Cineraria have been interpreted in a sense of which I did not dream when I wrote them.

I wish, therefore, to say that, although I do not believe Mr. Bateson's reading of the passages I quoted to be the true one, yet I have never questioned his sincerity in suggesting it, and I am pained to find that I have seemed to do so.

May 24. W. F. R. Weldon.

Boltzmann's Minimum Function.

I gather from Mr. Culverwell's last letter (Nature, April 18), and Mr. Bryan's (May 9), that we may regard the following conclusion as established, namely, the proof of the H theorem, for any system depends on a certain condition (A) being fulfilled among the coordinates and momenta of the molecules forming the system. Considering these as elastic spheres, and using Dr. Watson's notation, $f dp_1 \ldots dq_3$ is the chance that a sphere shall have for coordinates and momenta $p_1 \ldots p_1 + dp_1$, &c., and $F dP_1 \ldots dQ_3$ the chance that another sphere shall have $P_1 \ldots P_1 + dP_1$, &c. The condition required is that f and F are independent, even for two spheres on the point of collision.

Otherwise we may express it. Let there be n spheres in space S. Let us suppose Mr. Culverwell to assign to each its position at time $t = 0$, and Mr. Bryan to assign independently to each its component velocities. Then the condition A is fulfilled when $t = 0$.

We can then prove that when $t = 0$ $\frac{dH}{dt}$ is negative, or, as Herr Boltzmann would have us say, is more likely to be negative than positive.

Now arises a question which seems to me to deserve consideration. Assuming our system to be finite, and to be left to itself unaffected by external disturbances, does it necessarily

[1] It has been impossible for me to incorporate in this letter all the mass of information which has been most generously sent me by correspondents since this controversy began. It is suggested that I should point out that Mr. Dyer's use of the word "feral" to mean "wild" is not usual. A correspondent tells me that it was probably first used in the special sense of "run wild" by Hamilton Smith, *Nat. Libr.*, *Mammalia*, 1839, ix. p. 92. It has since been so used by many authors, especially Darwin, *An. and Pls.* i. p. 117, &c.

follow that condition A, being now satisfied, will continue to be satisfied for all time?

If the answer be Yes, then of course $\frac{dH}{dt}$ will continue to be negative, until at length H reaches its minimum, and the system attains to perfection in the form of the Maxwell-Boltzmann law. If that is necessarily the future of our system, then, as Dr. Watson says, the Maxwell-Boltzmann law is not only a sufficient, but a necessary condition for permanence.

I am not aware, however, that this doctrine of (so to speak) final perseverance has ever been proved to be true. I do not think it can be regarded as axiomatic.

It seems to me that if we are to make our finite system reach perfection with any certainty, we must resort to the principle to which I appealed in my first letter on this subject—that every material system is constantly receiving disturbances from without, the effect of which is to keep condition A in working order, and so to make $\frac{dH}{dt}$ generally negative. Otherwise we must regard our system as only part of an infinitely extended system, the parts of which, when not too distant, mutually influence each other. S. H. BURBURY.

Research in Education.

IT is quite unnecessary for Mr. D. S. T. Grant to suffer "dialectic annihilation" (see p. 5) in order to discover Prof. Armstrong's definite scheme of scientific education, inasmuch as in 1889-90 such a scheme was published by a Committee of the British Association, of which Dr. Armstrong was an active member.

As I believe many schools are still waiting for evidence as to the practicability of the scheme before adopting it, I venture to quote my own experience. I have been engaged for some time in practically applying this method to the teaching of girls of various ages, and am in a position to state that the scheme is perfectly workable.

It is not, of course, suggested that students should find out every known fact in chemistry or physics by a process of personal research—life is not long enough; but, if their early training be on these lines, they are in a much better position later on to accept, or if necessary reject, the work of others. A scientific method of thinking is of far more value than an accumulation of facts, and so it is extremely important that children should begin this kind of work before their logical perceptions have become obliterated by a continued application to irregular verbs. The problems set to young children are naturally of a very simple nature, and I do not leave the girls to themselves to "struggle to the truth by a process of trial and error." I state the problem to the class, and I usually find the girls have plenty of suggestions to offer as to its solution; these suggestions I criticise, and as soon as a practicable method has been found, the girls work it out for themselves. The early problems involve measurements of length, area, volume, and weight, and naturally the use of each new instrument is explained and illustrated. Simple physical problems follow these, such as experiments on relative density, and thus children are led to realise and appreciate the common properties of matter. After this training they are much more ready to solve elementary chemical problems. Certainly they could never work long enough to discover Dalton's laws for themselves, but they can quite appreciate classical experiments, and see how theory supplies an explanation of the facts. I am quite aware that if children are to work in this way they cannot be expected to sit still in their places with the look of passive receptivity on their faces, which is conventionally regarded as the proper appearance of well-disciplined scholars. They must move about, and should be encouraged to talk to each other about their work. I am convinced that a class of about eighteen is quite large enough if sound work is to be done; and if at any time their excitement becomes noisy, I find that a threat of numerical problems is quite sufficient to make them continue their practical work more peacefully.

It seems to me that physiology and hygiene, as usually taught in girls' schools, are absolutely pernicious and unscientific. Girls learn a list of the circulatory organs as they do the kings of England, and with less advantage. It would be considered criminal in them to doubt any of the facts in their books, although many are wrong, and yet, I take it, scientific training misses a great point if it does not engender a wholesome spirit of doubt. But the worst feature of all is the way in which girls are taught certain things in theory of the meaning of which they have not the faintest notion. They can tell one that water is H_2O, but the real significance of the symbol is perfectly unknown to them, and of course they are not able to understand it without some chemical training, in spite of the fact that some schools consider themselves very advanced and practical if the lessons are emphasised by the burning of hydrogen and the manufacture of oxygen. Numberless examples of similarly useless facts could be quoted, which are learnt under the name of hygiene—teachers, parents, and girls vainly believing that this is science. But all these facts are forgotten as soon as some examination is passed, and nothing is left behind; whereas a logical system of scientific training produces an effect on the mind which it is impossible to overrate. Surely the aim of education should be to produce not people who are full of facts, but those who can make the best use of the brains they possess, who are clear-headed, and able both to perceive and take advantage of opportunities that may be afforded them.

Central Foundation School for Girls, London. L. EDNA WALTER.

The Bibliography of Spectroscopy.

IT will be within the recollection of many of your readers that, in the year 1879, a committee was appointed by the British Association to report on the state of our knowledge of spectrum analysis, and I was asked to undertake the preparation of a bibliography of spectroscopy from the year 1870. It was not thought necessary to begin at an earlier date, for a bibliography of the subject is to be found in Roscoe's "Spectrum Analysis." With the help of several members of the committee, lists of spectroscopic papers were prepared, and appeared in the British Association Reports for 1881, 1884, and 1889. In that year Mr. H. J. Madan kindly consented to join the committee, and as he was then resident in Oxford he was able to afford valuable assistance in checking the references, and the section of the list that was published last year is almost entirely his work, as I had found it impossible to spare the time to go to London to look up the references in the libraries. Mr. Madan is now living in Gloucester, and therefore out of reach of scientific libraries; he has, notwithstanding, shown his interest in the subject by making frequent visits to Oxford and London to continue the work. He finds, however, that the work is hardly practicable for one so far removed from the great centres; and my object in writing this letter is to ask if any one will volunteer to relieve him from this duty—that is, on the supposition that the list is of real use to workers on spectroscopic subjects. Many of the readers of NATURE will be able to give valuable opinions on this matter, and probably to suggest improvements in the manner in which the list is drawn up.

It has been suggested that the four sections of the list should be rearranged and published as one continuous catalogue. The advantages of this for the purpose of reference are obvious; but from an estimate obtained last year, the cost of printing would not be less than £100. Dr. Tuckermann also very kindly proposed that the "Bibliography of Spectroscopy" drawn up by him and published by the Smithsonian Institution in 1888, should be incorporated with the British Association lists; this would very materially increase the expenditure.

Mr. Madan is quite willing to undertake gratuitously the literary work involved in the collection and rearrangement of the various sections. But the expense of publication is so great that the British Association can hardly be expected to bear the whole of it, although it is quite likely that a liberal grant might be made. Probably also grants might be obtained from other societies interested in the work, if it appears that the catalogue would be of special utility to those engaged in research. The balance might be met by a moderate charge for each copy sold.

Cooper's Hill, May 15. HERBERT MCLEOD.

An Aquatic Hymenopterous Insect.

NO doubt many of your readers are aware that, in 1863, Sir John Lubbock gave an account of an extraordinary hymenopterous insect which he had observed swimming in a basin of water taken from a pond at Chislehurst. Another observer (Mr. Duchess, of Stepney) had also found a single specimen about the same time; then, in 1881, Mr. Bostock found one in some pond water at Stone, Staffordshire, since which time it does not appear to have been recorded by any one. I have searched many ponds for it year after year, but without success.

On Saturday, May 4, the Quekett Microscopical Club held one

rs excursions in search of pond life, the neighbourhood visited being Totteridge and Mill Hill. Mr. W. Burton obtained two small phials of the water for examination, and the first pipette of water turned out into the trough contained a minute fly, which Mr. Burton kindly brought to me, when I immediately identified it as the *Polynema natans* (Lubbock, *Trans. Linn. Soc.*, vol. xxiv. 1864, p. 135, plate 23).

As this capture was, for the fourth time, the result of chance, Mr. Burton and I set out (May 6) to search for more specimens. After dipping our nets in and carefully examining the contents for over two hours, my patience was at last rewarded by seeing a beautiful female, struggling to free its wings from the mass of minute vegetation gathered in the dipping net. After a few hours more search, I found four males, which, together with the female, I transferred to an observation tank, where all soon disported themselves in the liveliest manner, swimming, or rather flying, under water for over four days, during which period they did not, to my knowledge, once leave the water. I have since obtained others, which are under close observation, and in course of time I hope to trace out their life-history.

Perhaps, owing to the microscopic dimensions of many of the *Mymaridæ* (Haliday), very few entomologists have paid any attention to this most interesting and fascinating family of beautiful "Fairy Flies," to whose industry we are no doubt largely indebted for our freedom from "blights" of many kinds. They are, indeed, mere specks, scarcely visible to the eyes of ordinary folk, and yet they have their place in nature.

I am inclined to think that when the type collection of the *Mymaridæ*, made by the late Mr. Haliday, has been thoroughly examined, this name *Polynema natans* will have to give place, so far as the genus is concerned. I hope that before very long we shall have figures of all the genera in this most interesting group.

FRED. ENOCK.

Halley's Chart.

I HAVE been much interested with the letter of Dr. L. A. Bauer in your last number, as I happen to possess a map, or chart, bound up with a number of Dutch, German, and French maps of the end of the seventeenth and the first years of the eighteenth centuries. The latest map with a date is 1704. This English map is evidently the same as 974 (4) mentioned by Dr. Bauer. It is entitled "A new and correct chart showing the Variations of the Compass in the Western and Southern Oceans, as observed in ye year 1700, by his Maties command by Edm. Halley." The dedication reads as follows, in Latin: "Majestati semper Augustæ Gulielmi III. D.G. Magnæ Britanniæ Fra. & Hib. Regis Invictissimi. Tabula hæc Hydrographica Variationum Magneticarum Index. Devotissime Consecratur a Subdito Humillimo Edm. Halley." At one side of the map is the following: "The curve lines which are drawn over the seas in this chart do show at one view all the places where the variation of the compass is the same: The numbers to them show how many degrees the needle declines either Eastwards or Westwards from the true North: and the double line passing near Bermudas and the Cape de Virde isles, is that where the needle stands true without variation."

The chart is in excellent condition, but has no name of printer on it. The only indication is "J. Harris, Sculp." The course of a vessel going from and returning to England is clearly marked.

THOS. WARD.

Northwich, May 27.

ON THE LINE SPECTRA OF THE ELEMENTS.

I THINK Lecoq de Boisbaudran was the first who called attention to the fact that the line spectra of the elements are by no means so irregular as they seem to be at first sight. He discovered the similarity in the spectra of the alkalies and alkaline earths, and pointed out how the lines in the spectra of these two families seem to be shifted towards the less refrangible side with increasing atomic weight. Mascart, in 1869, found two strong triplets of lines in the ultra-violet spectrum of magnesium, similar to the strong green triplet so prominent in the solar spectrum. He says: "Il semble difficile que la reproduction d'un pareil phénomène soit un effet du hasard; n'est-il pas plus naturel d'admettre que ces groupes des raies semblables sont des harmoniques qui tiennent à la constitution moléculaire du gaz lumineux? Il faudra sans doute un grand nombre d'observations analogues pour découvrir la loi qui régit ces harmoniques." But the wave-lengths corresponding to these rays were then not accurately known, and so the most interesting feature concerning the oscillation frequencies, or the number of waves which pass any fixed point in unit of time, remained unnoticed. It was later on shown by Hartley, that the differences between the wave-numbers of the three lines seem to be the same for all the triplets. This constant difference of wave-numbers repeated in a number of doublets, of triplets, and of more complicated groups of lines, has now been observed in the spectra of many elements. There are repetitions of doublets in the spectra of sodium, potassium, rubidium, cæsium, copper, silver, aluminium, iridium, thallium; of triplets in the spectra of magnesium, calcium, strontium, zinc, cadmium, mercury, manganese, and of more complicated groups of lines in the spectra of tin, lead, arsenic, antimony, bismuth. In all these cases the differences seem to be absolutely constant. For, notwithstanding the great accuracy with which Rowland has taught us to determine the wave-lengths, the law holds good. As an example, I give the list of doublets in the spectrum of thallium, according to Prof. Kayser's and my determinations. The number of waves passing a fixed point in unit of time, is equal to the distance the light travels in unit of time divided by the wave-length. If we measure the wave-lengths in vacuo, the distance the light travels is the same for all rays. We may then choose as unit of time, the time that light requires to travel one centimetre, so that the wave-number is simply equal to $1/\lambda$, λ being the wave-length in vacuo, measured in centimetres. In this manner, we get rid of the necessity of settling the velocity of light, which as yet has not been measured with anything like the accuracy with which the wave-lengths are known.

The mean of the twelve differences, assuming their weights to be inversely proportional to the square of the estimated limit of error, is 7792·5. When the wave-lengths are not reduced to vacuo, the differences are also very nearly constant, because the reduction alters them all nearly by the same amount. But it was a source of satisfaction to me, that the reduction brought all the deviations from the mean value well within the limits of error, whereas without the reduction the second difference had been just beyond the limit. These twelve doublets do not comprise half the number of wave-lengths that have been

observed in the spectrum of thallium. But, nevertheless, I think any one will agree that their numerical relation is no chance coincidence. Let us now make a drawing of these doublets to the scale of $1/\lambda$. Evidently the twelve first lines will give the same picture as the twelve second lines. Let us therefore, to simplify matters, only plot down the twelve first lines. At first glance this does not show any remarkable regularity; but if we drop the fourth and sixth line, we can arrange the rest in two series, as is shown in Fig. 1, both rows resembling the series of lines in the spectrum of hydrogen, which are so accurately represented by Balmer's formula. Recurring now to the general list of lines observed in the spectrum of thallium, we find that all five lines of the first series are accompanied on their more refrangible side by strong and easily reversed lines, while the lines of the second series are single. Thus not only does the symmetry of the drawing justify the separation of the lines into two series, but their that only four lines out of sixty do not show any signs of a system according to which they are grouped.

I have given this detailed account of the arc spectrum of thallium only as an example; for I might describe many more spectra that show a similar regularity in the distribution of many of their lines. But there is another interesting point. The distribution of lines in the spectra of chemically related elements shows evident signs of a common plan. I will, for instance, describe the series of triplets in the spectra of magnesium, calcium, and strontium.

The most prominent lines in the visible spectrum of magnesium are the three green lines 5184, 5173, 5168 10^{-8} cm. forming the group *b* in the solar spectrum. In the ultra-violet, at least ten repetitions of this group have been observed, two more being doubtful on account of their weakness and nebulosity. The differences of wave-numbers have been found to be the same in all the groups,

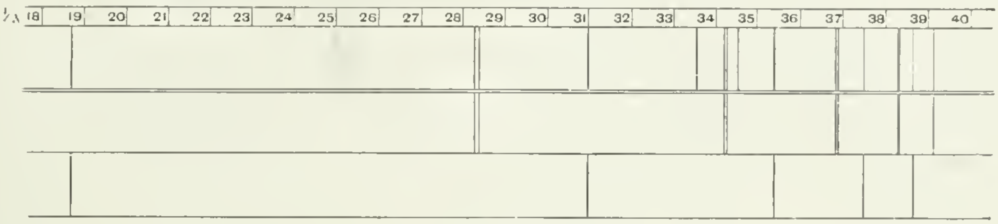

FIG. 1.

appearance teaches us the same. We may expect to find that a formula similar to that of Balmer connects the lines of each of these two series. Indeed, for suitable values of A, B, C the wave-numbers may be calculated from the formula,

$$A - Bn^{-2} - Cn^{-4}$$

A and B having nearly the same values for both series, and n assuming the values 4, 5, 6, 7, 8 for the first, and 3, 4, 5, 6, 7 for the second series. One may state the formula thus: if the wave-numbers be plotted as ordinates to the abscissæ $1/3^2$, $1/4^2$, $1/5^2$, &c., the points form a parabola. If we now go on substituting for n the subsequent whole numbers, we find that all these calculated wave-lengths really exist in the spectrum. But they are weaker and weaker for higher values of n. Prof. Kayser and I have been able to observe the wave-lengths calculated by the formula of the first series for $n = 9$, 10, 11, 12, 13, 14, 15, 16, and by the formula of the second for $n = 8$, 9, 10, 11, 12, 13, 14, 15. We searched for the second members corresponding to these lines, but could not detect them, owing to our plates not being sensitive enough for wave-lengths as small as 2100. However, they have nearly all been observed by Cornu. If we accept Cornu's wave-lengths, we now have two series of doublets of equal width in the scale of wave-numbers, and a drawing of them shows a remarkable symmetry (Fig. 2). The drawing comprises 47 out of 60 lines that constitute the arc spectrum of thallium, including Cornu's observations. Of the thirteen lines left, five are the strong lines, mentioned above, that accompany the five first lines of the first series on their more refrangible side. The distance between each line and its companion grows smaller as we advance to smaller wave-lengths, the last distance being not more than 0·45 10^{-8} cm. It seems probable that the next lines also have their companions, which, however, so closely coincide with them that it has not been possible to separate them. So there are only eight lines left, the positions of which do not enter into the general plan of the spectrum. Among these eight lines there are two doublets of the same difference of wave-numbers as all the other doublets. Both widen asymmetrically—one towards the more refrangible side, the other to the less refrangible side. Thus we may say

as may be seen from the following list. The wave-lengths have not been reduced to vacuo, because all three lines of one group are so near one another that they would all be changed by nearly the same amount, so that the differences of wave-numbers would practically remain the same.

In the sixth triplet, the first line has not been observed. There is a very strong line 2852·22 not far from where the

first line of the triplet should be. But this one is out of the question on account of its enormous energy, which would be quite out of comparison with the other lines. So we must suppose that the first line of the triplet is concealed by the strong line. Indeed, on the plates Prof. Kayser and I have examined, it would be impossible to detect a line close to 2852. Again, as in the spectrum of thallium, these triplets form two series (see Fig. 3), and again we find that the wave-numbers of the first, second, and third lines in each series are very accurately represented by a formula,

$$A - Bn^{-2} - Cn^{-4},$$

n standing for the row of entire numbers. For each series there are three values of A, but only one value of B, and

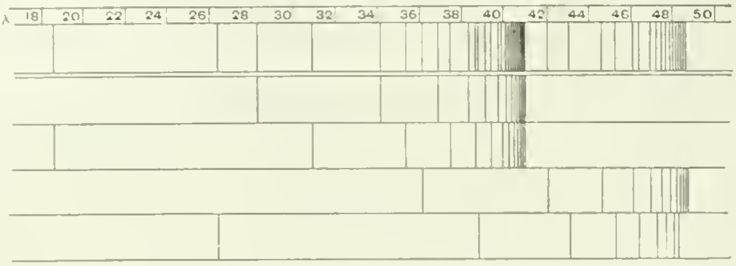

Fig. 2.

one value of C. The three values of A are very nearly the same in both series, indicating that the ends of both series coincide. The lowest number for which the formula gives a positive value is $n = 3$. To this value corresponds the strong green triplet. But in the other series the corresponding triplet ought to be found near 13000 10^{-8} cm. where photographic methods fail. It may be that it is identical with the lines that Becquerel has found near 12000 and 12120, the first of which, he says, is possibly double. The deviation between these and the calculated values is not so very great, considering the wide extrapolation of the formula. A small change in the value of C would alter the formula much more for $n = 3$ than for the higher values of n. Besides, we believe the formula only to be an approximation to the true function which may be developed into a series of descending powers of

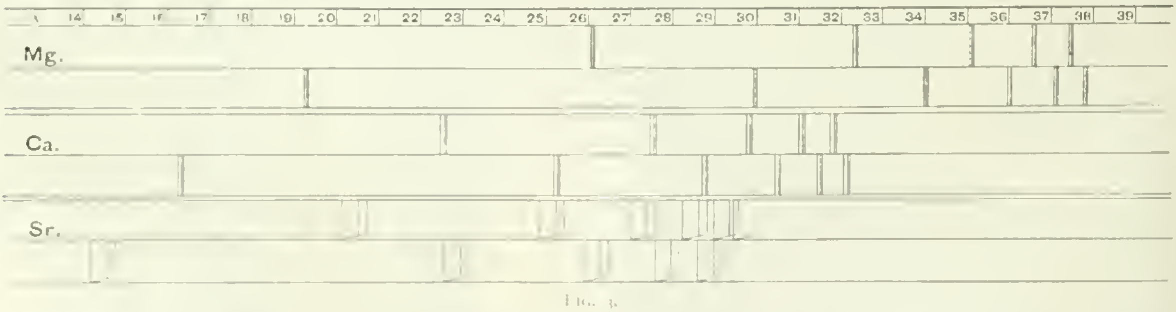

Fig. 3.

n^2. If this is so, the neglected terms world affect the values of the formula much more for the low values of n, than for the higher ones. The separation of the triplets into two series is not only suggested by the symmetry of the distribution, but also by the aspect of the lines.

In the spectra of calcium and strontium, we also find triplets with the same differences of wave-numbers, and their appearance teaches us in each spectrum to separate them into two series. We then see that the distribution of triplets shows a remarkable similarity to that in the spectrum of magnesium.

The dotted lines in the figure mean that the corresponding rays have not been identified with certainty. There are many lines beside those forming the triplets. For magnesium, the triplets contain 33 out of 56 lines, for calcium 33 out of 106, for strontium 29 out of 97. We have found that, as a rule, the higher the melting point of an element, the greater is the percentage of lines in the arc spectrum that do not belong to the series. From magnesium to calcium, and from calcium to strontium, the triplets widen and shift to the less refrangible side of the spectrum. The same thing happens in the spectra of other groups of chemically-related elements, the difference of wave-numbers of the doublets or triplets being somewhat proportional to the square of the atomic weight.

There is one more feature which seems interesting in regard to the connection of the spectra of different elements. In all the formulæ of series that have been observed, the coefficient of n^{-2} does not vary more than about 10 per cent. from its mean value, if we except one of the two series of doublets in the spectrum of aluminium where the variation is somewhat larger. I think, when in some time a satisfactory theoretical explanation of the symmetry in the spectra of the elements will be given, this co-efficient will prove to be an important physical constant.

C. Runge.

KARL VOGT.

THE life of Prof. Karl Vogt, who died on May 6, was no tranquil scientific career, for he was a fighting philosopher. He first comes into notice in 1839, working with Agassiz, then Professor at Neuchatel, on the "Freshwater Fishes of Central Europe." This great work, never completed, determined the direction of Vogt's best research during the rest of his long life. It was only in 1888–94 that the "Traité d'Anatomie Comparée," by Vogt and Jung, was published in Paris, taking high rank as a standard authority, and likely to retain it. He returned from Paris to his native town of Giessen, where he had been appointed Professor. But the revolution of 1848 soon burst forth, and we hear of him as an advanced Democratic Deputy contending for liberty and progress with the trenchant oratory he could use alike in politics and science. Political forces were too strong against him, and

he had to depart from his university and country, finding a home again in Switzerland, where he took up the double life of biologist and politician as a Professor at Geneva, and a prominent member of the National and Federal Council. His all-round knowledge is testified to by papers on Alpine geology, petrology, and prehistoric archæology. Those who were present at the Norwich meeting of the Congress of Prehistoric Archæology in 1868, remember his robust presence and slashing speech. To this subject, at the time rising into notice, belong Vogt's discourses, well known in the English translation, edited by Dr. James Hunt, and published by the Anthropological Society in 1864 under the title "Lectures on Man: his Place in Creation, and in the History of the Earth." There is so much forcible reasoning in this book, that it may still be read with profit thirty years after date. It is true that the thesis of the book which gained it favour with the polygenist school, whose desire was to trace the races of mankind to several locally and specifically distinct origins, is one which would nowadays hardly find supporters among anthropologists. Vogt held that the various branches of the human race trace their pedigrees to corresponding branches of the anthropomorpha. He cannot see "why American races of man may not be derived from American apes, Negroes from African apes, and Negritos, perhaps, from Asiatic apes." In these lectures Vogt shows a by no means admirable mode of controversy by unpleasant epithets, more or less like those which, in Germany as elsewhere, the orthodox world had poured on "infidels" and "materialists." But his sense of humour was blunt, and he evidently did not see that religion, which has swayed the universal human mind from untold ages, is a cosmic force which, by its very immensity, should be out of the reach of jokes like calling a low-type cranium an "apostle-skull." Even more remarkable in this respect is Vogt's "Köhlerglaube und Wissenschaft," an invective in the name of science on the credulous piety which, in countries where the trade of the charcoal-burner is plied, finds its best example among these isolated ignorant forest-folk. To the newer school of anthropologists, the term "charcoal-burner's belief" suggests quite a different sense. One would sit down by them and question them in order to find surviving in their minds ideas which are fossils from the most ancient times.

As a zoologist Vogt's reputation rests upon less equivocal grounds. The subject supplied him with fewer opportunities of displaying his anti-theological bias, and he brought his great powers to bear upon a number of problems, with the result that he added largely to the progress of zoology. His writings are numerous, and range over a wide variety of subjects; and he by no means confined himself to comparative anatomy, but made observations which entitled him to honourable rank among physiologists. In his "Traité d'Anatomie Comparée" he tells us, in the preface to the second volume, that he has studied and dealt monographically with no less than twenty-two types of animals, belonging to nearly every class of the animal kingdom. Much of this work was begun in the earlier part of his career, when he published many papers and several monographs upon the forms which he has afterwards chosen as types in his text-book. He was an active embryologist in earlier days, and wrote on the development of Filaria (1842), Batrachia (1844), Cephalophora (1856), and Crustacea (1873). In 1853 he published observations on the fertilisation of the ovum. He made a special study of the Siphonophora in 1852–54, and produced in 1868 an admirably illustrated monograph, entitled "Recherches sur les Animaux inférieurs de la Méditerranée," which deals with Siphonophora and pelagic Tunicata. His work on Branchipus and Artemia, published in 1872, is well known. Vogt's activity did not decrease with advancing years, as is testified by his contributions to current scientific literature and the publication of his text-book. His abilities were great, and he had a keen appreciation of the importance of the special problems of zoology to which he directed his attention. But his interests were too various, and his work ranged over too great a number of subjects, to admit of his rising to the position of a first-rate authority in any one of them. Had he applied himself solely to one course of study he would, by his powers of investigation and his vigorous method of exposition, have found a place among the foremost biologists of the century. As it was, he dissipated too much energy and thought in attempting to grasp too wide a range of knowledge.

E. B. T.
G. C. B.

At the meeting of the Paris Academy on May 6, M. Blanchard referred in the following terms to the part Vogt took in the study of the formation and movement of glaciers, under the direction of Louis Agassiz.

"At the beginning of August 1845, Agassiz arrived at the hospital of Grimsel, accompanied by Carl Vogt, Desor, Nicolet, and two students from Neuchatel. They brought their instruments with them, for they had come with the idea of determining the temperature of the glaciers, of studying the form of the snow, and of ascertaining in what manner the *névé* forms itself into ice.

"They had with them two very experienced men as guides; they resolved to take up their position on the smaller glacier of the Aar, which is of special interest; the surface is strewn with masses of rock, which produces an effect of a heap of ruins. On approaching the moraine, the investigators perceived that the glacier had advanced considerably since the previous year. A hut, left by Hügi, one of the first explorers, had disappeared.

"After a brief survey, they fixed the place of installation near a large block, and the guides set to work to build a small house large enough to hold six people. The walls were built of dry stones; large flagstones served as boards; beds were made of layers of grass, covered with oilcloth and other coverings, and were thought perfect.

"As a matter of fact, the opening which gave access to the house was very small, but still Carl Vogt could enter, and where Carl Vogt could pass every one could. Instead of a door, a curtain was put up. In the night, before going to bed, it was decided that the dwelling should be called the "Hôtel des Neufchâtelois": this name was, therefore, cut on the rock in big letters, and time has consecrated it.

"Does not this reunion of young savants in the solitude, in the middle of a nature both grand and sad, offer a curious spectacle to the imagination? The noises of the pleasures of this world and of public affairs does not ascend as far as the hut on the glacier of the Aar: aspirations and joys, unknown to most mortals, agitate the hearts there. These men, who without effort, without regret, renounce comfort for many a long day, dream of penetrating into the deepest secrets of nature; they discuss gravely most formidable questions, and laugh over many incidents. Agassiz never loses his good humour, and Desor abandons himself to joking. Carl Vogt, always sparkling with fun, and himself capable of enlivening an assembly of monks, effectually prevents the possibility of *ennui*.

"Amongst the investigators, who are stirred by the same thought, peace is never broken; on the sea of ice, with no other witnesses than the blocks of granite, and the peaks covered with eternal ice, there are no rivals. In proportion to the extent of his aptness every one sets himself with energy to the common work. Agassiz is the undisputed chief, the recognised master. To bring a stone to the monument he was building, was the only thing the zealous workers cared about.

"They rose early at the 'Hôtel des Neufchâtelois': on the stroke of four they had to be up. The time of dressing was rather trying, as the water was so cold and made them shiver; but that over, nothing more was thought of than continuing their research. Agassiz volunteers to bore holes; the ice can only be cut with great difficulty, for it resists the instruments. While this operation is being done, Carl Vogt examines the red snow, the strange hue of which is due to the presence of myriads of microscopic beings; he discovers many kinds of infusoria, and a pretty rotifer sowing the snow with its purple-coloured eggs.

"Carl Vogt was never inactive; in the last years he published, together with M. Jung, a treatise on zoology. Every one will acknowledge that a life so well spent is an honour to humanity." W.

NOTES.

SCIENCE is but poorly represented in the list of the Queen's birthday honours. Lord Playfair, previously a K.C.B., has accepted the honour of G.C.B. Rear-Admiral W. J. L. Wharton, Hydrographer to the Navy, has been made a Companion of the Order of the Bath. Mr. W. M. Conway, whose climbs in the Himalayas led to the publication of some interesting scientific results, has been knighted.

DR. E. FRANKLAND, F.R.S., Correspondent of the Paris Academy of Sciences, has been elected Foreign Associate, in the place of the late Prof. van Beneden.

DR. ESMARCH, of Kiel, has been elected a Correspondent of the Paris Academy of Medicine.

PROF. THOMSEN, who has been a Corresponding Member of the French Academy of Inscriptions since 1860, has been elected a Foreign Associate, in the place of the late Sir H. Rawlinson.

THE *Times* correspondent at Melbourne says that a meteorological observatory has been established on the summit of Mount Wellington, Tasmania.

A MILLION acres of forest land has been reserved by the Province of Ontario as a great natural park for the preservation of native animals and plants.

THE discourse at the Royal Institution to-morrow evening will be delivered by the Earl of Rosse, the subject being, "The Radiant Heat from the Moon during the progress of an Eclipse." That on June 7 will be by Prof. A. Cornu, F.R.S. This lecture will be delivered in French, and the title will be, "Phenomenes Physiques des Hautes Régions de l'Atmosphere."

THROUGH a gift of Mr. W. C. McDonald (says *Science*), McGill University has secured thirty-five acres of land for botanical gardens and an observatory. From the same source we learn that the residue of the estate of Mary D. Peabody has been left to the Catholic University of Washington, for the foundation of scholarships (probably three or four of the value of 5000 dollars each) in the chemical and physical sciences.

AMONG the appointments abroad, we notice that Dr. N. V. Ussing has accepted the Professorship of Mineralogy in the University of Copenhagen. Dr. F. Karsch has become Extraordinary Professor of Zoology in Berlin University, Prof. Emil Behring has become Ordinary Professor of Hygiene at Marburg, and Dr. Zaremba (privat-docent in mathematics at Krakau) has been promoted to an Extraordinary Professorship.

THE electrical power developed at the Niagara Falls will soon take the place of steam for several hundred miles distance from the Falls, including New York City. An important proposed application is to the Erie Canal, which has just opened for the season. Experiments will be made for applying the power by a trolley system, and the reduction of expense will probably drive out all other means of transportation for grain, &c., from Buffalo to tide water, during the season of navigation.

AT the International Horticultural Congress, opened at Paris on Saturday, resolutions were unanimously adopted to the effect: "(1) That the French Government should associate itself with the request addressed by the Italian Government to the Swiss Confederation, with a view of obtaining the revision of the Berne International Convention, and the free circulation between all countries signatory to the convention, of all vegetables and vines, accompanied by a certificate of origin; and (2) that the postal administration should return to the old reduced tariff, of which periodical publications on horticulture have hitherto had the advantage."

EFFORTS are being made (says the *American Naturalist*) to raise a fund of 12,000 dollars for the purpose of bringing Mr. Peary and his two assistants home from North-west Greenland early next autumn, and, in connection with this, to prosecute scientific investigations during the available summer season. It is hoped, by this means, to charter and fit out a staunch steamer, built for Arctic service and commanded by experienced Arctic navigators, which shall start from St. John's, Newfoundland, on or about July 5, 1895, for Inglefield Gulf, North-west Greenland, lat. 78 N., Mr. Peary's headquarters.

WE have received a notice concerning three "Priestley" Scholarships in Chemistry, two "Bowen" Scholarships in Engineering, and one in Metallurgy, which have been founded by the late Mr. T. Aubrey Bowen, of Melbourne. They are intended to encourage and afford facilities for the higher study of these subjects in Mason College, where they are tenable for one year, with the possibility of renewal at the discretion of the Council of the College. The annual value of each is £100. Although, naturally, good work done at Mason College will be regarded as a specially favourable qualification, the Council have generously thrown all the Scholarships open to general competition. The first award will be made in September next, and all particulars may be learned on application to the Secretary of the College.

THE gold medal of the Linnean Society has this year been awarded to Prof. Ferdinand Cohn, of Breslau, whose name is well known in connection with the *Botanic Journal*, which he has conducted, largely adorned with his own contributions, from 1870 to the present time. The work of Dr. Cohn extends over half a century. He was one of the earliest to investigate the life-history of the lower Algæ, and to demonstrate that they are not asexual. His important paper on *Protococcus pluvialis*, published so long ago as 1850, was translated by Busk for the Ray Society. Subsequent papers by him, on the mode of reproduction of *Sphaeroplea annulina*, and on the development of *Volvox*, mark a distinct advancement in botanical science. The medal referred to was awarded to him at the anniversary meeting of the 24th inst., and has been forwarded to Breslau, for his acceptance, through the German Embassy.

AT the anniversary meeting of the Royal Geographical Society, held on Monday, the Founder's Medal was presented to Dr. John Murray for his services to physical geography, and especially to oceanography during the last twenty-three years, also for his maps of the floor of the ocean, his calculations regarding the volume of continents and oceans, his study of the origin and formation of coral deposits, and for the stimulus he has given to researches in physical geography. The other awards were the Patrons' Medal, to the Hon. George N. Curzon, M.P., (1) for his work on the history, geography, archæology, and politics of Persia; (2) for his journeys in

French Indo-China, which have resulted in further publications of geographical as well as political and general value: and (3) for his journey to the Hindu Kush, the Pamirs, and the Oxus, together with a visit to the Amir of Afghanistan, in his capital of Kabul. The Murchison Grant, to Mr. Eivind Astrup, for his remarkable journey, with Lieut. Peary, across the interior glacier to the northern shores of Greenland: and for his independent journey along the shores of Melville Bay; the Back Grant, to Captain C. A. Larsen, for the geographical and meteorological observations made by him during his Antarctic voyage in 1894, and for his discovery of an active volcano on Christensen Island, of several other islands, and of part of the east coast of Graham Land; the Gill Memorial for 1895, to Captain J. W. Pringle, R.E.; and the Cuthbert Peek Grant for 1895, to Mr. G. F. Scott-Elliot, for his explorations of Mount Ruwenzori, and of the region to the west of the Victoria Nyanza.

WE wish the American Metrological Society success in its efforts to extend the use of the metric system in the United States, and to procure general agreement with regard to the constants of science. Its objects are ambitious, as the following statement of them, from *Science*, will show: (1) To improve existing systems of weights, measures and moneys, and to bring them into relations of simple commensurability with each other. (2) To secure universal adoption of common units of measure for quantities in physical observation or investigation, for which ordinary systems of metrology do not provide, such as divisions of barometer, thermometer, and densimeter; amount of work done by machines; amount of mechanical energy, active or potential, of bodies, as dependent on their motion or position; quantities of heat present in bodies of given temperatures, or generated by combustion or otherwise; quantity and intensity of electro-dynamic currents; aggregate and efficient power of prime movers; accelerative force of gravity; pressure of steam and atmosphere; and other matters analogous to these. (3) To secure uniform usage as to standard *points of reference*, or physical conditions to which observations must be reduced for purposes of comparison, especially temperature and pressure, to which are referred specific gravities of bodies, and the zero of longitude on the earth. (4) To secure the use of the decimal system for denominations of weight, measure, and money derived from unit-bases, not necessarily excluding for practical purposes binary or other convenient divisions, but maintained along with such other methods, on account of facilities for calculation, reductions, and comparison of values, afforded by a system conforming to our numerical notation.

ON January 18, the great seismometrograph at the Osservatorio del Collegio Romano at Rome registered five complete pulsations of slow period characteristic of earthquakes originating at a great distance. They commenced at 4h. 37m. 30s. p.m. (Greenwich mean time), and lasted 1m. 22s., giving an average duration of 16·4 seconds for each pulsation. On the same day a severe earthquake was felt along the east coast of Japan, and was recorded at Tokio at 3h. 48m. 24s. The distance between this place and Rome being about 9500 km., the pulsations must have travelled with an average velocity of 3·2 km. per second (see NATURE, vol. l. pp. 450-51; vol. li. p. 462). At Nicolaiew and Charkow, in the south of Russia, the horizontal pendulums were disturbed for nearly an hour, the epoch of maximum amplitude occurring a few minutes earlier than at Rome.

MR. MARSHALL HALL publishes in the *Alpine Journal* (vol. xvii. p. 438) a note on the progress made in the study of glaciers, for which purpose a Committee was appointed at the meeting of the International Congress of Geologists at Zürich. Good work appears to have been done, in exploring and mapping, among the glaciers of New Zealand, in the course of which Franz-Joseph Glacier, on the west coast, was found to end at a height of 692 feet above the sea, and a distance of four miles from it. The rate of movement is, of course, variable: an average of the observations (with certain omissions) gives 154·2 inches per diem. Valleys containing large glaciers give indications that the ice has been higher than it is at the present day, and has paused at four different levels. Work also has been done among the glaciers of the eastern side of New Zealand, and a few facts are recorded; among them, that in advancing the ice appears not to plough up the earth. In conclusion, Mr. Marshall Hall calls upon mountain climbers to help in the work of the Committee.

A PAPER on "The Brain of the Microcephalic Idiot," by Prof. D. J. Cunningham, F.R.S., and Dr. Telford-Smith, read before the Royal Dublin Society nearly a year ago, and noticed at the time in these columns (NATURE, vol. l. p. 287), has just been published in the Society's *Transactions*. The authors give the results of a thorough examination of the brains and skulls of two typical microcephales. Their study leads them to accept the view arrived at by Sir George Humphry, from an examination of microcephalic and macrocephalic skulls, viz.: "There is nothing in the specimens to suggest that the deficiency in the development of the skull was the leading feature in the deformity, and that the smallness of the bony cerebral envelope exerted a compressing or dwarfing influence on the brain, or anything to give encouragement to the practice lately adopted in some instances of removal of a part of the bony case, with the idea of affording more space and freedom for the growth of the brain. In these, as in other instances of man and the lower animals, the brain-growth is the determining factor, and the skull grows upon and accommodates itself to the brain, whether the latter be large or small."

DR. W. M. HAFFKINE has brought together his Indian experiences in anti-choleraic inoculations, and has published them in the *Indian Medical Gazette*. In spite of the very numerous difficulties which he had to encounter in carrying out his investigations, Dr. Haffkine has succeeded, with the assistance of others, in inoculating no less than 32,166 individuals with his cholera vaccine. Every pains was taken to obtain trustworthy records of the results derived from these inoculations, and, as far as can be judged from the data to hand, the balance appears to be decidedly in favour of the process. This is perhaps especially brought out by Dr. Haffkine's work in Calcutta, where the percentage of attacks and deaths amongst the inoculated was 1·18 per cent., whilst amongst the non-inoculated the percentage of cases amounted to 15·63 per cent., and of deaths 11·63 per cent. One fact has indisputably been established by these investigations, and that is the harmlessness of the operation; in view of this it is to be hoped that the inoculations may be more widely spread, and further facilities thus offered for the collection of observations on this very important subject.

A YEAR'S actinometric observations, made at the Konstantinow Observatory, Pawlowsk, are recorded by J. Schukewitch in the *Repertorium für Meteorologie*. They have led to some unexpected results regarding the intensity of the sun's radiation at different seasons of the year. This intensity, as measured on the surface of the earth, depends upon the altitude of the sun and upon the transmitting power or opacity of the atmosphere. The intensities were measured by a thermometer with blackened bulb, which was exposed to the sun side by side with a precisely similar one which was kept in the shade. To test whether the two thermometers were identical in their behaviour, two successive readings were taken, in which first the one and then the other was shaded. It was found necessary to take the mean of these two readings in each case. The tables embodying the results contain, besides the intensity, the state of the sky, the altitude of the sun, and other meteorological data. From these tables the yearly course of intensity of the unclouded sun at noon

is worked out. It shows a principal maximum in April, a secondary maximum in September, and chief minimum in November. The intensity of solar radiation for equal altitudes is greatest in winter and least in summer, a circumstance which tends to equalise the winter and summer temperature. A great diminution of transmissibility is brought about by that phenomenon so characteristic of the middle-European continent, called in Germany *Höhenrauch*, an elevated stratum of peat-smoke which gives a faint and rather pleasant odour, usually taken to indicate the continuance of fine weather. The author finds greater opacity in front of an atmospheric depression, and greater transmissibility after it. The clearest air is preceded by a heavy summer rain.

THE Meteorological Council have published a valuable set of monthly meteorological charts of the Red Sea, showing the prevalent winds and currents, with other information of use to seamen passing through the Suez Canal to India. The wind observations alone number nearly 75,000, and have been supplied from logs specially kept for the Meteorological Office, from ships belonging to the Royal Navy, and various other sources. Each chart, of which there are twenty-four, contains useful remarks referring to the leading features, which are shown graphically, and the introduction to the Atlas contains an interesting general summary by Lieutenant C. W. Baillie, R.N., Marine Superintendent. The wind charts show that from October to January northerly winds are prevalent over the northern half of the sea, and southerly over the southern portion. From February to May the northerly winds extend further south, while southerly winds prevail from near Perim to about the 16th parallel. From June to September, northerly winds blow over nearly the whole sea. Gales are most frequent between November and March; they generally blow from the southward, and are mostly met with in the southern part of the sea. The currents are somewhat erratic, and while occasional strong streams are experienced locally, their velocity is not usually great over large areas. The Gulf of Aden may be taken as an exception, as the currents often set there with considerable velocity. An interesting feature has been noticed in the range of sea-temperature in the Strait of Bab-el-Mandeb, near the Island of Perim, where it amounts to 20° at the period of the S.W. monsoon. The whole work shows evidence of the great care and labour bestowed upon it.

THE extent to which many of the American agricultural experiment stations are devoting attention to the culture of small fruits and other minor crops is perhaps significant of an impending change in the economic bearings of the management of the soil, and of the partial displacement of the *grande culture* which has hitherto almost monopolised the field of experimental inquiry. Bulletin No. 55 of the Purdue University Station, Lafayette, Indiana, opens with a description of experiments with small fruits, carried out in response to the numerous inquiries received from farmers and others concerning the different varieties of such fruits. Strawberries, raspberries, blackberries, currants, gooseberries, and grapes, form the subject of this section of the report. Field experiments with maize and oats are next dealt with, and amongst the results noted, it is stated that better yields have followed the sowing of two bushels or more of oats per acre than that of any smaller quantity. The bulletin concludes with a notice of experiments with sugar beet; but in view of the desperate condition to which the beet-growers of France are at present reduced, despite the artificial support which the sugar industry there receives under the bounty system, we cannot see any immediate hope for the American beet-sugar industry. This, indeed, is practically admitted in the bulletin, for it is said: "The condition of the sugar business throughout all sugar producing countries is such that there seems to be little probability of capital being invested in beet-sugar plants in this country at present." The points which are reported upon include comparison of varieties, time of harvest, the respective effects of bacterial disease and beet scab on the sugar content of beets, the effect of loosening beets some time before lifting them from the ground, special thinning, tests of foreign and American seed, and yield and cost of crop per acre. It is concluded that, under more favourable economic conditions, beet factories might advantageously be established in the State of Indiana.

A PAPER by Wilhelm von Bezold, on the lines of equal disturbance of the magnetic potential of the earth, appears in a recent number of the *Sitz. der Akad. der Wiss. zu Berlin*. The deviation of the potential at any place from the mean value of the potential corresponding to the parallel of latitude passing through this place being called the disturbance, the author gives the theory of the lines of equal disturbance. He shows that the westerly (or easterly) component of the earth's magnetism is given by the rate of change of the disturbance of the potential along the parallel of latitude or $W = \frac{\partial Va}{\partial y}$ where Va is the disturbance for the potential, and ∂y is an element of a latitude circle. Hence it follows that a knowledge of a westerly component of the earth's field for the whole surface of the earth suffices to everywhere determine the disturbance in the magnetic potential, and draw the lines of equal disturbance. Wherever the lines of equal disturbance are tangential to a circle of latitude $\frac{\partial Va}{\partial y} = 0$, and hence $W = 0$, or all such points will lie on the agonic lines, *i.e.* the lines along which the declination is zero. At all places where the lines of equal disturbance are tangential to the terrestrial meridian the northerly component of the earth's field has its normal value. The author has constructed a chart of these lines for the epoch 1880, using the data given in the magnetic charts published by G. von Quintus Icilius. The mean value of the magnetic potential for the latitude λ is found to be given with a high degree of accuracy by the expression $V_n = K \sin \lambda$, and the author considers that this simple expression must have some special significance, and not be merely an empirical formula.

A PAPER, by Mr. G. C. Whipple, entitled "Some Observations on the Growth of Diatoms in Surface Waters" (*Technological Quarterly*, vol. vii.), is a valuable contribution to the study of the periodic frequency of microscopic organisms in freshwater areas. The work is noteworthy as having been carried on in a biological laboratory attached to the Boston Water Works. The author's general results are here given: (1) That the growth of diatoms in ponds is directly connected with the phenomena of stagnation; that their development does not occur when the lower strata of water are quiescent, on account of greater density, but rather during those periods of the year when the water is in circulation from top to bottom. (2) That diatoms flourish best in ponds having muddy bottoms. (3) That in deep ponds there are two well-defined periods of growth—one in the spring and one in the autumn; that in shallow ponds there is usually a spring growth but no regular autumn growth, and that other growths may occur at irregular intervals as the wind happens to stir up the water. (4) That the two most important conditions for the growth of diatoms are a sufficient supply of nitrates and a free circulation of air, and that both these conditions are found at those periods of the year when the water is in circulation. (5) That while temperature has possibly a slight influence on the growth of diatoms, it is of so little importance that it does not affect their seasonal distribution. (6) That the increase of diatoms takes place substantially in accordance with the law of geo-

metrical progression, and that the cessation of their growth is caused by the diminution of their food supply.

Mr. H. G. Wells's scientific fantasy, the "Time Machine," which has been appearing as a serial in the *New Review*, will be published in volume form, by Messrs. Heinemann, in the course of a few days.

Mr. Gisbert Kapp has arranged with Messrs. Whittaker and Co. for a translation from the German of his new work on the "Alternate Current Transformer." The volume will be published in the "Specialists' Series" in the autumn.

The papers on the relation of diseases of the spinal cord to the distribution and lesions of the spinal blood-vessels, recently contributed by Dr. R. T. Williamson to the *Medical Chronicle*, have been reprinted and published in book form by Mr. H. K. Lewis.

This week's new editions include Prof. T. Preston's philosophical "Theory of Light," published by Messrs. Macmillan. More than one hundred pages of new matter have been added, a valuable addition being an account of Prof. Newcomb's experiments to determine the velocity of light. The second edition has appeared of the late Prof. Cayley's "Elementary Treatise on Elliptic Functions" (Macmillan), the first edition of which was published in 1876. Another second edition, received during the past week, is "A First Book of Electricity and Magnetism," by Mr. W. Perren Maycock. This book, now greatly enlarged, is published by Messrs. Whittaker and Co.

The Deutsche Seewarte, which, with the year 1894, has completed its twentieth year of useful activity, has just issued the seventeenth volume of *Aus dem Archiv*. This work, which has contained many elaborate and valuable discussions in meteorology, navigation, and nautical astronomy, is now devoted more especially to discussions of practical utility to seamen. Among the articles of more general scientific interest may be mentioned one by Dr. Grossmann, on the application of Bessel's formula in meteorology, and one by Dr. Maurer, on the application of graphical methods in meteorology and physics generally; the latter investigation may possibly lead to the substitution of this method for the use of tables in some of the problems of nautical astronomy.

The additions to the Zoological Society's Gardens during the past week include six Hairy-footed Jerboas (*Dipus hirtipes*), two Lesser Egyptian Gerbilles (*Gerbillus ægyptius*), two Lybian Zorillas (*Ictonyx lybica*), two Grey Monitors (*Varanus griseus*), two Egyptian Mastigures (*Uromastix spinipes*), three Egyptian Geckos (*Tarentola annularis*), a Common Chameleon (*Chamæleon vulgaris*), seven Common Skinks (*Scincus officinalis*), two Cerastes Vipers (*Vipera cerastes*), two Diademed Snakes (*Zamenis diadema*), from Egypt, presented by Dr. John Anderson, F.R.S.; a Grysbok (*Neotragus melanotis*, ♀), from South Africa, presented by Mr. J. E. Matcham; a Wapiti Deer (*Cervus canadensis*, ♀), a Japanese Deer (*Cervus sika*, ♀), a Burchell's Zebra (*Equus burchelli*, ♂), two Polar Hares (*Lepus glacialis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Mercury and Venus.—The planet Mercury is now an evening star, and will be favourably placed for observation until towards the end of June. The greatest elongation will occur on June 4 at 13h., when the planet will transit about 1h. 42m. after the sun; the declination will then be nearly 25° north, and the apparent diameter a little over 8". Jupiter will be in close proximity to Mercury during the present period of its visibility, so that observers not employing telescopes must be careful to discriminate between the two; at the elongation, Mercury will precede Jupiter by about 8m. in R.A., and will be about 1½ degrees farther north. The two planets will be in actual conjunction on June 8 at 4h., Mercury being 0° 47′ N. of Jupiter.

Venus, also, is most favourably situated for observation at the present time, and the great brilliance of the planet in the western sky after sunset cannot fail to attract the attention of the most indifferent. It will not, however, reach maximum brightness until August 13. The greatest eastern elongation will occur on July 11, and the apparent diameter will increase from 16" on June 1 to 59" at the inferior conjunction on September 18.

The Total Solar Eclipse of 1898 January 21–22. In addition to the eclipse of the sun which will take place on August 8, 1896, and for which we understand preparations are already well in hand, there will be another important solar eclipse before the end of the present century. This will occur on January 21–22, 1898, and the *Nautical Almanac Circular*, No. 16, gives local particulars of the same for that portion of the path of the shadow which lies across India. At Rajapur the duration will be 2m. 1·9s. and the altitude of the sun 53°; at Nagpur, 1m. 17·7s. with an altitude of 46°; and at a position south of Benares, 1m. 43·6s. with an altitude of 40°. Information as to the meteorological conditions prevailing at various points along the track of the eclipse during the latter part of January is being collected through the assistance of Mr. Eliot, Meteorological Reporter to the Government of India. It is proposed to publish this information early in 1897.

As the next sun-spot minimum is not due until the year 1900, observations of the phenomena of this eclipse will furnish information as to the solar conditions during the transition from maximum to minimum.

The Astro-photographic Chart.—The third part of the second volume of the *Bulletin* of the International Permanent Committee, gives an account of the present state of the great undertaking to prepare a photographic catalogue and chart of the heavens. The reports from the various participating observatories indicate in general a rapid advance towards the completion of the photographs which are intended to form the basis of the catalogue; four of the eighteen observatories have already completed the zones allotted to them, and it is expected that at least eight more will reach this stage by next spring. Systematic work at the South American observatories has been seriously interfered with by political events; but it is satisfactory to learn that the Australian and Cape of Good Hope astronomers are prepared to come to their assistance. An immense number of catalogue plates with short exposures has been taken with the various instruments, no less than 753 having been taken at Paris, and 1562 at the Cape. The measurement of the catalogue plates is also in a forward state at several of the observatories, but the reductions have scarcely been commenced.

For the chart itself, not one-third of the requisite photographs have yet been obtained, but the progress of this part of the work is necessarily slow, in consequence of the long exposures required.

Dr. Gill proposes that the Committee should meet in 1896, to reconsider the various questions left open at the former conference, among which one of the most important relates to the scale of magnitudes to be adopted.

Four important memoirs also form part of the present report. Prof. Turner and M. Prosper Henry discuss different methods of reducing the plates. M. Trépied gives his experience and views as to the determination of magnitudes, and M. Donner discusses the various corrections for instrumental errors.

Award of the Watson Medal.—On the recommendation of the Board of Trustees of the Watson Fund, the U.S. National Academy of Sciences last year unanimously awarded the Watson medal to Dr. S. C. Chandler, for his investigations relative to variable stars, his work in connection with the variation of terrestrial latitudes, and his researches on the laws of that variation. The recommendation was noted in these columns a year ago, and a description of the founding of the award was given (Nature, vol. l. p. 157). The medal was presented to Dr. Chandler at the recent meeting of the National Academy, and *Science* for May 3 contains the report of the Trustees, setting forth the grounds upon which the award was made, and briefly stating the history of the investigation of changes of latitude. Dr. Chandler's work upon the subject began with observations made by him in 1884–85. His observations, continued uninterruptedly for thirteen months, revealed a progressive change of a pronounced periodical character in the

instrumental values of the latitude. Circumstances prevented him from carrying on the work until six years later, when he took up the problem again. The results then obtained are published in a series of eighteen papers in the *Astronomical Journal* (1891–94), exclusive of a series of five papers upon a topic closely related thereto, namely, the aberration-constant. These papers have been noted from time to time in this column, so it is unnecessary to do more than refer to them now.

In connection with variable stars, besides the incidental work of observation and discovery which Dr. Chandler has contributed to it, his work has involved the collection of all the data in astronomical history, their discussion, and the formulation of the elements of their light-variations into numerical laws. His important researches upon cometary orbits are also well known to astronomers.

A LECTURE EXPERIMENT.

A FURTHER description of the use of the electric furnace recently exhibited at the Royal Society, for the purpose of lecture demonstrations, may be useful, as pictures, some six feet across, of the interior of the furnace may readily be projected on the screen. This is effected by the aid of the device which has already been given in NATURE (p. 17, Fig. 2). The result is really very beautiful, though it can only be rendered in dull tones by the accompanying illustration (Figs. A, B). It may be well, therefore, to state briefly what is seen when the furnace is arranged for the melting of metallic chromium. Directly the current is passed, the picture reflected by the mirror, E (Fig. 2, *loc. cit.*), shows the interior of the furnace (Fig. A) like a dark crater, the dull red poles revealing the metallic lustre and grey shadows of the metal beneath them. A little later these poles become tipped with dazzling white, and, in the course of a few minutes, the temperature rises to about 2500 C. Such a temperature will keep chromium well melted, though a thousand degrees more may readily be attained in a furnace of this kind. Each pole is soon surrounded with a

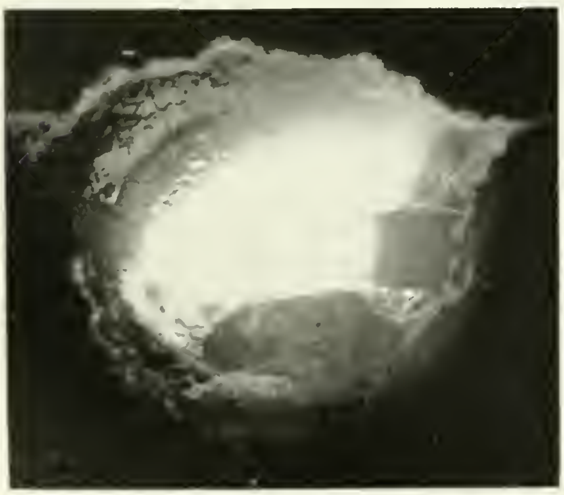

FIG. A.—This represents the interior of the furnace containing molten chromium as is seen either by reflection on a screen or by looking into the furnace from above, the eye being suitably protected by deeply tinted glasses.

lambent halo of the green-blue hue of the sunset, the central band of the arc changing rapidly from peach-blossom to lavender and purple. The arc can then be lengthened, and as the poles are drawn further and further asunder, the irregular masses of chromium fuse in silver droplets, below an intense blue field of light, passing into green of lustrous emerald; then the last fragments of chromium melt into a shining lake, which reflects the glowing poles in a glory of green and gold shot with orange hues. Still a few minutes later, as the chromium burns, a shower of brilliant sparks of metal are projected from the furnace, amid the clouds of russet or brown vapours which wreath the little crater; while if the current is broken, and the light dies out, you wish that Turner had painted the limpid tints, and that Ruskin might describe their loveliness.

The effect when either tungsten or silver replaces chromium is much the same, but, in the latter case, the glowing lake is more brilliant in its turbulent boiling, and blue vapours rise to be condensed in iridescent beads of distilled silver which stud the crater walls.

FIG. B.—In this case the arc was broken the instant before the photograph was taken. The furnace contained a bath of silver just at its boiling point. The reflection of the poles in the bath, the globules of distilled silver, and the drifting cloud of silver vapour, are well shown.

Such experiments will probably lend a new interest to the use of the arc in connection with astronomical metallurgy, for, as George Herbert said long ago—

> "Stars have their storms even in a high degree,
> As well as we";

and Lockyer has shown how important it is, in relation to such storms, to be able to study the disturbances in the various strata of the stellar or solar atmosphere. Layers of metallic vapour which differ widely in temperature can be more readily obtained by the use of the electrical furnace than when a fragment of metal is melted and volatilised by placing it in the arc, in a cavity of the lower carbon. W. C. ROBERTS-AUSTEN.

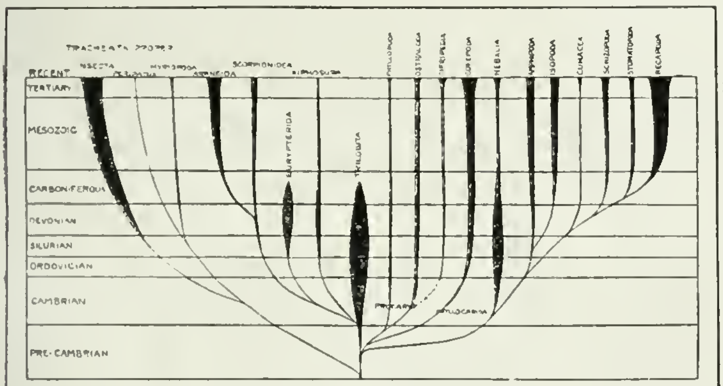
THE LIFE-HISTORY OF THE CRUSTACEA IN EARLY PALÆOZOIC TIMES.

IN his recent anniversary address to the Geological Society, the President, Dr. Henry Woodward, F.R.S., after the usual distribution of medals and awards, the reading of obituaries of deceased Fellows, and some preliminary matters relating to the affairs of the Society, including the moot question of the introduction of ladies as visitors to the evening meetings, devoted the remainder of his address to a brief discussion of "Some Points in the Life-history of the Crustacea in Early Palæozoic Times." Dr. Woodward continued as follows:—"Of the various groups of the Invertebrata whose ancestry extends into Palæozoic times, none possess a greater interest for the geologist than the Crustacea, whose existence is proved as far back as the Lower Cambrian rocks; while their near allies, the Arachnida, have been met with in strata as old as the Silurian.

"My earliest papers on the Eurypterida appeared in 1863 and 1864, and an account of *Stylonurus* and *Hemiaspis* was communicated to this Society in 1865, just thirty years ago. In that year (1865) I had the pleasure, with my friend and fellow-worker, the late J. W. Salter, F.G.S., of publishing a 'Chart of Fossil Crustacea,' in which an attempt was made to show the evolution in time of the various forms belonging to this class, graphically depicted on an engraved folding-sheet, with explanatory text. In it we pointed out that the main development of the crustacea in Palæozoic times consisted of the great groups of the Trilobita, the Eurypterida, the Xiphosura, the Phyllopoda, and the

Ostracoda. The faint beginnings of other great groups were also indicated, such as the Macrouran-decapods represented by *Anthrapalæmon* and other forms in the Coal Measures; the Stomatopods by *Pygocephalus Cooperi*, the Amphipods by *Gampsonyx*, both in the Coal Measures: and by *Prosoponiscus* in the Permian. Lastly, the Cirripedia, by the anomalous form *Turrilepas*, from the Wenlock Limestone.

"In November 1866, I laid before this Society the evidence upon which I based my arrangement of the *Pterygoti* and *Limuli* in one order, for which I adopted Dana's very appropriate name of Merostomata (or 'thigh-mouthed' animals)—expanded to include all those ancient crustaceans comprehended in the two sub-orders of Eurypterida and Xiphosura, and forming two groups of long-bodied and short-bodied forms, quite parallel to the Brachyoura and Macroura in the Decapoda; even the intermediate forms—corresponding to the Anomoura—being paralleled by the Hemiaspidæ (*Hemiaspis*, *Pseudoniscus*, &c.). This group formed the subject of a monograph published by the Palæontographical Society (1865–1878) comprising 17 genera and 84 species—69 of which are Palæozoic in age. The integrity of this group, founded on the researches of Huxley, Salter, Dana, Hall, and many others besides myself, has been firmly maintained, although many attempts have since been made to detach it from the Crustacea and place it with the Arachnida. For instance, it was proposed by Dr. Dohrn, in 1871, to include the Merostomata in a still larger division, under Haeckel's term Gigantostraca, which was made by expansion to embrace the Merostomata and the Trilobita, and to be placed *between* the Crustacea and the Arachnida.



THE EVOLUTION OF THE ARTHROPODA IN GEOLOGICAL TIME.

"In arguing for their retention before this Society in 1871 I wrote:—'Take away the trilobita from the pedigree of the crustacea, and I submit that one of the main arguments in favour of evolution to be derived from the class, so far from being strengthened, is destroyed. From what are the crustacea of to-day derived? Are we to assume that they all descended from the phyllopods and ostracods—the only two remaining orders whose life-history is conterminous with that of the trilobita? Or are we to assume that the arachnida are the older class?' 'If,' says Fritz Müller, 'the crustacea, insecta, myriapoda, and arachnida are indeed all branches of a common stock, it is evident that the water-inhabiting and water-breathing Crustacea must be regarded as the original stem from which the other terrestrial classes, with their tracheal respiration, have branched off.'

"In the above-quoted paper I pointed out that the young *Limulus*, when it quits the egg, has the hinder body as large as the head-shield, and the nine segments composing it are most clearly marked out, the abdominal spine being quite rudimentary and forming in fact the 9th segment. This is the so-called '*Trilobiten-stadium*' of Dohrn.

"'At this stage,' says Packard, 'the young swim briskly up and down, skimming about *on their backs* by flapping their gills, not bending their bodies.' This locomotion of the young *Limulus*, by swimming upon its back, near the surface of the water (by means of its gill feet), agrees very closely with the habit of *Apus*, of *Chirocephalus*, and *Artemia*, and is extremely suggestive of its affinity to the phyllopoda, with which, at this stage of its existence, it has many points in common, as well as with the trilobita.

"It is interesting to notice that the Xiphosura (king-crabs)—which form the surviving representatives of this ancient order of the Merostomata, and are so widely distributed in the Coal Measures of North America, Britain, &c.—have likewise been discovered as far back in time as the Upper Silurian of Lanarkshire, being represented by a small form which I named and described, in 1868, *Neolimulus falcatus*, having eight thoracic segments apparently free and movable, but wanting the tail-spine, which probably was developed later in life, or may have been represented by an extremely short terminal plate, as we see is the case in the young larval *Limulus*. Thus the earliest fossil king-crab known probably resembled closely the free-swimming larva of the living king-crab as it leaves the egg.

"As to whether the Eurypterida—with their evidently aquatic branchiated respiration, their jaw-feet provided with swimming- (not walking-) extremities—are in the direct line of ancestral relationship to the recent scorpions, I may refer again to my paper 'On some Points in the Structure of the Xiphosura,' &c.:—'This is one very strong argument, to my mind, in favour of the higher zoological position of *Pterygotus*—that, being extremely larval in its anatomy, it consequently possessed the capacity for further development, and so has been modified and disappeared'—its latest representatives being met with in the Coal Measures, where the then earliest known examples of fossil scorpions had also been found. But the discovery, almost simultaneously, by Thorell and Lindström in Gotland; by B. N. Peach in Scotland; and by Whitfield in North America (in 1885) of actual pulmonated land scorpions in rocks of Upper Silurian age (as far back, in fact, in geological time as the earliest known occurrences of *Pterygotus*, *Slimonia*, and *Eurypterus*) indicates that the air-breathing scorpions were derived from a *still earlier* and as yet undiscovered aquatic progenitor possibly in Cambrian or pre-Cambrian times.

"Simultaneously with the commencement of my own work on the Merostomata, J. W. Salter undertook a monograph on the British Trilobites for the Palæontographical Society in 1864. No one who takes up this fine work of our old friend can avoid a feeling of regret that Salter's valuable life and splendid palæontological knowledge should not have been longer spared to us to carry on to its completion this most important service.

"Following up the progress of our knowledge of the trilobites, I may note that Dr. Henry Hicks made his first communication to this Society in 1865 on the genus *Anopolenus*, and between 1871 (when he came to London from the happy hunting-grounds of St. David's and joined the Geological Society) and 1876, he communicated to this Society a series of papers on the faunas of the 'Menevian,' the Lingula Flags, Tremadoc Slates, and Arenig series, giving descriptions of no fewer than thirty-four species of trilobites, belonging to eighteen genera, from those ancient rocks.

"But numerous as are these additions to our knowledge of the trilobites of Wales, they only represent a part of Dr. Hicks's discoveries, many of which were announced by Salter; the most important being that of the finding of a large *Paradoxides* at St. David's, proving the existence of a Middle Cambrian or '*Paradoxides*-zone,' coextensive with the vast area over which these early rocks have been observed, and occupying a persistent horizon throughout Europe and America.

"A brief reference must here be made to the papers published by that excellent geologist and naturalist, the late Thomas Belt, F.G.S., in 1867 and 1868, on new trilobites from the Upper Cambrian rocks of North Wales, and on the Lingula Flags or Ffestiniog group of the Dolgelly District, with figures and descriptions of four species of *Olenus* (non-*Conocoryphe*) and four species of *Agnostus* from Dolgelly. In 1888 I was so fortunate as to be able to record the first discovery of trilobites (*Conocoryphe viola*) in the Longmynd Group, Penrhyn quarries, Bethesda, near Bangor, in North Wales.

"The remarkable fauna of the *Olenellus* or Lowest Cambrian zone, originally discovered in America by Dr. Emmons in 1844, was first recognised in Europe by the late Dr. Linnarsson in 1871, in the basal zones of the Cambrian near Lake Mjösen in Norway, but its typical genus *Olenellus* was then referred by him to the allied but more recent genus *Paradoxides*. This referenc

was corrected by Prof. Brogger in 1875; and the various brilliant papers on the Primordial formations by this author have given the *Olenellus*-fauna a marked and peculiar interest. In 1882 Linnarsson next made known the existence of the *Olenellus*-fauna in Scania, at the base of the Swedish Cambrian. In 1886 the same fauna was detected by Mickwitz in the Lower Cambrian of Russia (Esthonia), and this Russian fauna was figured and described in detail by Dr. F. Schmidt, of St. Petersburg. In 1887 Dr. Holm reported the existence of the *Olenellus*-fauna in the Cambrian of Lapland, where it was first detected by Morstell in 1885. Thus the existence of this remarkable fossil group, the oldest well-marked fauna recognised by geologists in the Lower Cambrian, had already been demonstrated, in 1888, in three main regions, namely: (1) in the region of the Rocky Mountains; (2) in the region of North-eastern America; (3) in the region drained by the Baltic Sea. Up to 1888 no recorded account of the discovery of *Olenellus* from the British Isles had been published, the oldest fauna described being the overlying *Paradoxides*-zones or Middle Cambrian formation.

"The first recognisable traces of *Olenellus* in Britain were discovered by Prof. Lapworth in 1885. Further collections were made in 1887 and 1888, on the flanks of Caer Caradoc, Shropshire, and the species was named, in honour of Dr. Charles Callaway, *Olenellus Callavei*. Later on it was figured and described in the *Geological Magazine* for 1891.

"In August 1891, Sir A. Geikie announced, at the British Association meeting in Cardiff, the discovery of *Olenellus* by Messrs. Peach and Horne, in blue-black shales, a few feet below the "Serpulite Grit" of the Cambrian rocks of North-west Scotland, in the Dundonnell Forest of Ross-shire. The description of "the *Olenellus*-zone of the North-west Highlands" formed the subject of a most valuable paper by Messrs. Peach and Horne, read before the Geological Society on February 10, 1892, and a new species of *Olenellus* is described and named *O. Lapworthi* by these authors. Mr. B. N. Peach, F.R.S., communicated a second paper, "Additions to the Fauna of the *Olenellus*-zone of the North-west Highlands," on June 20, 1894; in which, in addition to *O. Lapworthi*, he describes and figures *O. Lapworthi* var. *elongatus*, *O. reticulatus*, *O. gigas*, *O. intermedius*, and *Olenelloides armatus*.

"'The Fauna of the Lower Cambrian or *Olenellus*-zone' forms the subject and title of an admirable monograph by Mr. C. D. Walcott, F.G.S., which, with the exception of the subsequent discovery of an *Olenellus*-fauna in the Lower Cambrian of the Scotch Highlands (already referred to), gives us a very complete and up-to-date account of this interesting and oldest fauna. About eighteen widely distributed localities are shown on the map of North America from British Columbia to Labrador, and as far south as Texas; whilst in Europe we have Spain, North and South Wales, the Scottish Highlands, Norway, Sweden, Finland, Bohemia, Bavaria, Podolia, Sardinia, Petchoraland, and the Ural Mountains. Omitting trails, burrows, and tracks, the *Olenellus*-fauna has yielded fifty-five genera of organisms, fifteen of which are Trilobites.

"We may now add yet another locality in which this remarkable fauna occurs, as proved by the presence of the remains of *Olenellus* and the pteropod *Salterella*; namely, in Western Australia, where it was discovered by Mr. Hardman in 1886.

"I must here refer to the discoveries of the limbs of trilobites. In 1870 the late E. Billings, the Palæontologist of the Geological Survey of Canada, brought before the Geological Society and described a specimen of *Asaphus platycephalus*, from the Trenton Limestone of Ottawa, Canada, exhibiting remains of eight pairs of limbs, corresponding with the eight free and movable segments of the body, and showing the hypostome still attached to the doublure of the anterior border of the cephalic shield; traces of two appendages under the caudal shield were also visible. On that occasion I exhibited a specimen of *Asaphus* from the same locality and horizon, showing one or two small 7–8-jointed palpus lying at the side of the hypostome apparently in its original position. After some remarks on the superficial character of trilobites, I added: 'The prominence of the hypostome in the trilobita reminds one much more strongly of the genus *Apus* than of the isopods, and it seems reasonable to expect in the trilobita a more generalised type of structure than that which marks the modern representatives of the class.'

"In 1881, after many years of untiring labour, Charles D. Walcott furnished most conclusive proofs of the existence of appendages to the cephalic, thoracic, and abdominal divisions of *Calymene*, *Ceraurus*, and *Acidaspis*. His researches have been carried on by the method of making thin transverse and longitudinal sections of rolled-up specimens. He has shown that the ventral body-wall of the trilobites was bounded inferiorly by a thin chitinous membrane, which was attached to the lower margin of the dorsal exoskeleton all round. This ventral membrane was supported by calcified arches, which gave attachment to the appendages beneath. He further established the existence of a row of articulated cylindrical limbs, on each side of the middle line. Walcott described the thoracic appendages in *Calymene* as slender six-jointed walking-legs (endopodites) with a single pointed termination, the basal segment giving rise to a branch appendage (exopodite). On each side of the throracic cavity he also described a row of bifid spiral appendages, of the nature of gills, and he suggested that branchiæ were attached to the bases of the thoracic limbs as well. The abdominal or pygidial rings carried appendages, a pair to each segment, but they do not appear to have differed from the thoracic limbs, save in size. The mouth is situated behind the hypostome, and has four pairs of jointed manducatory organs, the bases of which are modified to serve as jaws; the hindmost pair being the largest, and expanded at the distal extremity into a swimming-organ.

"The correctness of Billings's views, as to the nature of the thoracic limbs of *Asaphus platycephalus*, was further confirmed by the finding of a specimen of *Asaphus megistos*, in the Ordovician rocks of Ohio, which shows the under surface with its appendages, described by Dr. I. Mickleborough. This specimen shows two pairs of maxillipeds or jaw-feet, eight pairs of walking-appendages, corresponding to the eight pairs of free thoracic segments, each limb having about six joints. The under side of the coalesced segments of the abdomen (pygidium) reveals a series of from twelve to sixteen similar paired appendages, diminishing rapidly in size from before backwards to the extremity. A broad median groove extends along the under side of the thorax and abdomen, and probably represents the space once occupied by the sternites or, possibly, the straight intestinal canal, observed by Barrande in some trilobites from Bohemia. Traces of supposed branchial filaments have also been observed in this specimen, apparently attached to the thoracic legs.

"No further addition had been made to our knowledge of the appendages of triobites until July 1893, when Mr. W. D. Matthew, a student of Columbia College (N.Y.), communicated the result of his examination of several specimens of *Triarthrus Beckii*, obtained by Mr. W. S. Valiant from the 'Hudson River Shales' (Ordovician), near Rome, New York. After recording the extent of our previous knowledge derived from the important researches of C. D. Walcott, he proceeds to describe the additions which the specimens from Rome have supplied. These trilobites are found in a soft, fine, black shale, and are perfectly well preserved. The most noticeable character is the presence of long, slender, many-jointed whip-like appendages attached to the front of the head, closely resembling the flagellate antennæ of other crustaceans. These originate beneath the anterior border of the head-shield, and are as long again nearly as the glabella itself. Mr. Matthew also was able to detect a series of walking or swimming-legs, one a narrow, jointed, cylindrical leg, the other thin, broad, fringed with a comb-like structure similar to the gills of many crustacea.

"The next communication is from Mr. C. E. Beecher, of New Haven, Conn., 'On the Mode of Occurrence and the Structure and Development of *Triarthrus Beckii*.' The material gathered for the Yale University (by the aid of Prof. Marsh), near Rome, New York, is probably some of the best which has been obtained, and has been carefully examined and described by Mr. Beecher.

"In their present condition the specimens from Rome contain very little calcite, nearly the entire calcareous and chitinous portions of the trilobites being replaced by a thin film of iron pyrite. To this cause is doubtless due the preservation of delicate organs and structures which would otherwise have been destroyed.

"The specimens thus preserved occupy an extremely restricted vertical distribution, but within this range they are nearly all complete, and preserve their appendages. They are of all ages, from larval forms up to full-grown individuals, whilst the adjacent strata contain a rather sparse fauna in which the trilobites are generally fragmentary and without appendages. The author believes that, in the majority of beds in which trilobites are

found, the remains met with represent the exuviæ of living animals that have cast their shell, rather than the tests of dead individuals. In this particular deposit the appendages are apparently in the position which they occupied during life, and not such as would be assumed in the cast-off shells of recent crustacea.

"Mr. Beecher mentions another interesting point, namely, that nearly all the specimens are found with the back down, which is explained by suggesting that, although they lived with the ventral side downwards, the gases in the viscera produced during decomposition were sufficient to overturn the animal and allow it to be buried by the accumulation of the fine sediments in the position in which it is now found.

"The appendages of *Triarthus* appear now to be very well made out. The antennæ, as seen in a number of specimens, were simple multiarticulate flagella, which Walcott has shown extend backwards to the lateral margin of the hypostome, so that they occupy exactly the same position as do the first antennæ in recent *Apus*.

"Two small appendages, like simple palpi, with broad basal joints, which may represent the maxilla, are seen in one of Walcott's specimens, and there were probably four pairs of similar cephalic appendages, besides the simple flagellate antennæ, more or less modified to serve as mouth-organs.

"Each segment bears a pair of biramous appendages originating at the sides of the axis, as in other trilobites. The anterior legs are the longest, and the others gradually become shorter towards the pygidium. Each limb consists of two nearly equal branches, the 'endopodite' and 'exopodite,' which may be correlated with the typical crustacean primitive limb, and are well displayed in the adult *Mysis*; in the biramose natatory-feet of the zoea of the common shore-crab (*Carcinus*); and retained in the appendages of the abdomen of the adult lobster (*Homarus*). Practically, these biramose limbs are reproduced along the entire series of free segments. The appendages belonging to the pygidium closely resemble the branchigerous feet of *Apus*, and may evidently be correlated with typical phyllopod limbs.

"The first point insisted upon by all systematic zoologists—long before the finding of appendages had thrown so much new light upon our investigations—was that the great variability in the number of the segments in trilobites was a feature which distinctly connected them with the phyllopoda. Bernard considers of greater importance still the gradual diminution of the size of the segments posteriorly, which remarkable feature the trilobites share with *Apus*. I would also call attention to the fact that those earlier trilobites which best exhibit this large number of segments, such as *Olenellus*, *Paradoxides*, &c., are likewise remarkable for the simplicity and exact similarity of their segments, being a serial repetition of one another, and even the coalesced segments forming the head-shield share the same resemblance with the free posterior thoracic and abdominal ones. Bernard has given expression to the idea most aptly when he writes (*op. cit.* p. 412): "The adult is but the grown, not metamorphosed, larva—grown by the continual development of segments from before backwards, until at a certain stage this process becomes fixed, and we have the adult *Apus* with a number of fixed rudimentary segments. This fixation of a number of undeveloped segments is visible also in many trilobites.

"In the earlier forms (as *Olenellus*) these rudimentary posterior segments still remain free; but, as a rule, they are coalesced to form the plate-like pygidium so characteristic of the trilobites.

"Turning to the appendages, the simple multisegmented flagellate antennæ are extremely characteristic of the crustacea, being met with in lowly copepods and highly-developed decapods.

"The biramose paired limbs are quite a primitive type, like the segments to which they are attached, exceedingly simple, yet characteristic, and with the exception of the antennæ and the four succeeding pairs of appendages, which are modified to serve as mouth-organs (maxillæ and maxillipeds), the whole series are simple biramose natatory or walking-feet, such as persist still in adult *Mysis* and many other recent crustacea.

"The eyes in trilobites closely resemble those of other anthropods, but vary somewhat in position, and also in development, in some genera the eyes being altogether absent, as in *Ampyx*, *Ceraurus*, &c., whilst in others, like *Æglina*, they are enormously exaggerated in size. In some genera the eyes are hyaline, the faceted surface being covered with a fine transparent layer, whilst in others the facets appear prominently on the surface. It is suggested by Bernard that the minute pore observed in the head, near the compound eye in several genera (*Trinucleus*, *Acidaspis*, *Calymene*, *Ampyx*, *Griffithides*, *Phillipsia*, &c.), may be analogous to the pore in the head-shield of *Apus*, and be the opening into the water-sac covering the eyes; and whilst in some genera of trilobites this water-sac may have existed, it may have degenerated in others, leaving the eye in contact with the outer cuticle, which covered it like a thin transparent membrane. In none of the trilobites have larval eye-spots been observed.

"Dr. Lang held the view (in 1891) that if a fifth pair of cephalic limbs were found comparable with the anterior antennæ, trilobites might then be regarded as primitive entomostraca, to be derived from the same racial form as the phyllopoda.

"Walcott is of opinion that the trilobita formed a distinct branch, which diverged at a very early date from the phyllopoda, and having expended its vital energy in Palæozoic times it disappeared. He adds: 'Probably two thousand species and one hundred or more genera are known from Palæozoic strata. With this great differentation the initial vital energy of the group became impaired, and the trilobita died out at the close of Palæozoic time.

"I willingly adopt the view that the trilobita are ancestrally connected with *Limulus*; that *Limulus* may be related through *Hemiaspis* with *Eurypterus*; but all the intermediate forms have not yet been met with. That some ancestral Eurypterid must have given rise to *Scorpio* cannot, I think, be doubted; but it must have been in pre-Silurian times, for Peach and Lindström's *Palæophonus* had already appeared in the Upper Silurian of Lanarkshire and Gotland as a terrestrial pulmonated form, while a similar land-scorpion had been discovered by Whitfield in the Silurian of America.

"The Phyllopoda deserve consideration from a geological standpoint, a representative of *Apus* (*Protocaris Marshii*) having been met with in the Lower Cambrian of Vermont, U.S. Some of the living genera are naked (*Branchipus* and *Artemia*), but in most the front portion of the body is protected by a shield-like carapace (*Apus*), or it may be enclosed, as in *Estheria*, in a bivalve shell. The fossil remains of bivalved phyllopods, *Estheria* and *Leaia* were described by Prof. T. Rupert Jones as far back as 1862 in the Palæontographical Society, where he defines nineteen species ranging from the Old Red and Carboniferous upwards.

"The most ancient of these shield-bearing crustaceans, originally placed with the phyllopoda and having a single modern analogue (*Nebalia*), have now, by general consent, been removed and placed under the order Phyllocarida, a name suggested by Dr. A. S. Packard in 1879. The fossil forms referred to this order were originally studied and noticed by M'Coy, Salter, Barrande, Clarke, and have subsequently been fully described by Prof. T. Rupert Jones and myself.

"Metschnikoff, who studied the embryology of *Nebalia*, considered it to be a 'phyllopodiform decapod.' Besides the resemblance to the decapods, there is also a combination of copepod and phyllopod characteristics. The type is an instance of a generalised form, and is of high antiquity, having made its appearance in Cambrian times, when there lived (if we regard the relative size of most crustacea, and especially that of the living *Nebalia*) gigantic forms. Such was the Silurian *Ceratiocaris ludensis*, which was probably more than two feet in length.

"The modern *Nebalia* is extremely small, about ¼ inch in length, but a newly-described species, *Nebaliopsis typica*, Sars, measures as much as $1\frac{3}{5}$ inch, with the body compressed, and the carapace bivalved, as in *Limnadia*, one of the genuine phyllopods. There is a large movable rostrum overhanging the head: stalked eyes; the cephalic portion carries two pairs of antennæ and three pairs of special mouth-organs (mandibles and maxillæ); the thoracic segments bear eight pairs of short, leaf-like respiratory-feet, which are followed by six pairs of (abdominal) simple swimming-feet, four being large and two rudimentary, while the last two segments (seventh and eighth) are destitute of appendages, the body terminating in an elongated phyllopod-like caudal fork. Compared with *Nebalia*, the fossil forms give evidence of an articulated rostrum; traces of antennæ; the presence of a pair of strong mandibles; of a large expanded shield in some, and of a folded or bivalved carapace in others; of the presence of seven or eight body-segments, sometimes carrying branchigerous appendages, the terminal segment carrying a central caudal spine and two lateral shorter ones. It seems highly probable that the old giant pod-shrimps (*Ceratiocaris*, *Pithyrocaris*, &c.), whose remains occur in the Palæozoic rocks from the Cambrian to the Carboniferous, are represented by the

minute living *Nebalia*, and that these early forms may have given rise to, and have been the forerunners of, the modern Malacostraca. 'In *Nebalia*,' says Claus, 'we probably have to do with an offshoot of the phyllopod-like ancestors of the Malacostraca, which has persisted on to the present time.'

"The genus *Estheria* existed in the fresh and brackish waters of the Devonian Period, in Livonia, Caithness, and Orkney, and also in Nova Scotia and Scotland. It flourished in the European area at several of the Upper Carboniferous stages, and was well represented in the Secondary and Tertiary rocks: it is also living, and has a world-wide distribution.

"The Phyllocarida seem in some cases to afford examples of persistency of type, and in others of local or temporary specialisation. One of the oldest known is the Cambrian *Hymenocaris*, a prototype of the recent *Nebalia*. *Caryocaris* of the Arenig series possibly belongs to the same group; and the Upper Silurian *Ceratiocaris* carries the form to a high degree of perfection; but until we meet with the *Nebalia* of to-day we have no tangible links in this series in intermediate geological times. Walcott's Cambrian *Protocaris* is quite susceptible of being regarded as a predecessor of the living *Apus*. The Carboniferous *Dithyrocaris* and its allies stand probably in the relation of genealogical links. But much more research among these interesting lower crustacean fossils is required before their phylogenetic relationship can be fully elucidated.

"The Ostracoda, which have the entire body enclosed in a shell or carapace composed of two valves united along the back by a membrane (represented by such forms as *Cypris*, *Cypridina*, *Candona*, *Beyrichia*, *Primitia*, &c.), are chiefly dwellers in shallows, and occur both in fresh and salt water: they are usually of minute size; but there are deep-sea types which attain comparatively large dimensions (an inch long). They are met with in rocks of almost all ages from the Cambrian upwards. To speak of them here is to recall the nearly life-long labours (from about 1840) devoted to their elucidation by Prof. T. Rupert Jones, who has described many hundreds of these primitive crustacea from rocks of every British formation as well as from very many foreign countries.

"Great as are the transformations which these organisms have witnessed in the long cycles of geological change from Lower Cambrian to modern time, they present, nevertheless, a general facies, and (like the genus *Lingula* amongst the brachiopoda) must be looked upon as one of those persistent types which possess enormous power of multiplication, so that entire beds of rock may be said to be composed of their microscopic tests. The living species also possess exceptional powers of endurance and provision for the preservation of their lives in periods of drought, often retaining their vitality in a dormant state perhaps for years; thus they have persisted through all the vicissitudes of geological time, represented by the entire succession of the stratified rocks; 'all things changing, but themselves unchanged.'

"None of the older Ostracod genera exist now; but some of the existing forms of the Cyprididæ, Cytheridæ, and Cytherellidæ are fully represented by predecessors in the Palæozoic rocks. The wonderfully well-preserved *Palæocypris Edwardsii*, discovered by Dr. C. Brongniart, enclosed in transparent silica, displaying the soft parts of the animal as perfect as in life, from the Coal Measures of St. Etienne, is evidence of the existence of Cyprids in that far-off time.

"I have endeavoured to depict in a diagram (p. 115) the evolution of the Arthropoda in geological time.

"In concluding this brief excursion over the abysses of Palæozoic time, I have only been able to bring under your notice a few isolated points of interest in the crustacean fauna which lie in the depths of these ancient deposits. They may, however, serve to show that this group of lowly existences is not destitute of interest for the biologist. There may also be a possibility of connecting these isolated observations so as to show their bearing upon the greater question of the development of life.

"In order, however, to do this effectively I must ask you to accompany me next year in a second excursion over the newer Palæozoic and Kainozoic seas, where, nearer land and in shallower waters, we shall find a still greater variety of life-forms to study.

"Two conclusions may be drawn from our observations, namely, (1) that the ancient faunas of the earth were far more widespread, more ample and more uniform than are our recent faunas; and (2) if, as the researches of geologists seem to indicate, other sedimentary rocks exist, *older* than the Lower Cambrian, then we may hope to gather evidence of still earlier and more simple forms of life than are met with in the '*Olenellus*-zone.' We are fully justified in concluding that such must actually have existed, because we find in the Lower Cambrian evidence of a quite considerable fauna belonging to several divisions which, although lowly in themselves, are nevertheless already so clearly differentiated one from the other as to prove to us that we are still, both biologically and chronologically, very far removed from the commencement of life on the earth."

SCIENTIFIC SERIALS.

American Journal of Science, May.—On the colour relations of atoms, ions, and molecules, by M. Carey Lea. Part 1. The colour or absence of colour of an element is a function of its atomic weight. No element having ions coloured at all valencies can belong to the same natural group with elements having colourless ions only. The entire class of elements with colourless ions is divided into nine great natural groups, as follows:—H, F, Cl, Br, I; Li, Na, K, Rb, Cs; Ca, Sr, Ba; Sc, Y, La; Be, Mg, Zn, Cd, Hg; B, Al, Ga, In; C, Si, Ge, Sn, Pb, Th; N, P, As, Sb; O, S, Se, Te. This first great division of the elements includes all those whose ions function as anions, and also part of the cathions. Intermediate between the two chief divisions are eleven transitional elements, viz. Ti, V, Cu, Nb, Mo, Ag, Ce, Ta, W, Th, Bi. These have ions which at some valencies are coloured and at others colourless. These are cathions only. With atomic weights ranging from 1 to 47 the atoms are colourless; 52 to 59 coloured; 65 to 90 colourless; 103 to 106 coloured; 112 to 139 colourless; 145 to 169 coloured; 192 to 196 coloured. Elements whose place in the numerical series falls between these periods have both coloured and colourless atoms. The six heaviest metals at the end of the series are alternately coloured and colourless. Argon, Prout's hypothesis, and the periodic law, by Edwin A. Hill. A very interesting question connected with the discovery of argon is what will be the effect of these researches upon Prout's hypothesis? It is possible that argon has been an unsuspected cause of error, which, when properly allowed for, will show the ratio of H to O to be almost exactly 1 to 16. This would make so many atomic weights even or half multiples of H as to render probable the generation of the elements from a common form of matter by the continued addition of some one or more constant increments of mass.—Relation of the plane of Jupiter's orbit to the mean plane of 401 minor planet orbits, by H. A. Newton. The secular perturbation of the orbit of a minor planet by Jupiter is such that the inclination of the orbit plane is not greatly changed, but the node has a constant motion. Whatever may be the distribution of the poles of these orbits at one epoch, the tendency of the secular perturbation by Jupiter is to finally distribute them symmetrically around the pole of Jupiter's plane. The present inclination of the mean plane to Jupiter's plane is 0° 43'.

American Meteorological Journal, May.—The cause of cyclones, by Prof. A. Woeikof. The article deals chiefly with two points mentioned in a former paper on this subject by Mr. Dines. Dr. Woeikof considers that the balloon ascent from Munich on December 11, 1890, showed that, while there is no cooling of the free air in calm anticyclonic weather, the radiation of the surface of the snow cools the surrounding air, even on an isolated mountain. With regard to the suggestion that the latent heat set free by condensation is sufficient to cause a storm, he points out that the heat set free by copious condensation in India does not produce storms.—Meteorological problems for physical laboratories, by Prof. C. Abbe. Few physical laboratories have conveniences for studying aero-dynamics, but the author, with the assistance of Prof. C. F. Marvin, gives a list of thirty-seven subjects for experimental investigation which demand attention from meteorological students. Long range weather forecasts, by Prof. H. A. Hazen. The author puts forward a series of crucial tests of weather forecasts, more particularly with the view of showing the fallacy of the predictions based on the positions of the moon, planets, &c.—There is also an article by F. B. White on topographic influence on the winds of the weather maps, which frequently show erratic winds, having no dependence on the barometric gradients charted with them.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, May 10.—Captain W. de W. Abney, President, in the chair.—Mr. Herroun read a paper on the iodine voltameter. After referring to the usual methods of determining the value of the small currents used in calibrating galvanometers and other apparatus for measuring small currents, and discussing the errors to which they are subject, the author gave his reasons for selecting iodine. He did this since, with the exception of mercury in the mercurous state, iodine has the largest electro-chemical equivalent, and in addition, by titration with sodium thiosulphate, it is possible to determine the quantity of iodine liberated with a greater accuracy than can be obtained by weighing a deposit of copper or silver with the balance. The solution employed in the voltameter contains 10 to 15 per cent. of zinc iodide. If care is taken to leave a small piece of metallic zinc in this solution, no free iodine is liberated on keeping, unless the solution is exposed to a strong light for some time. The anode consists of a plate of platinum at the bottom of a tall and fairly narrow beaker. The wire leading the current to the anode is encased in a glass tube, so that the iodine is only liberated at the bottom of the beaker, where, on account of its great density, it tends to collect. The kathode consists of an amalgamated zinc rod, which, to prevent loose particles of zinc falling down into the iodine, is surrounded by a piece of filter-paper or vegetable parchment. In an electrolysis lasting for as long as two hours, none of the iodine is found to diffuse up to the part of the solution near the zinc kathode. Where, on account of the extreme feebleness of the current employed, it is necessary to allow the electrolysis to continue for longer than two hours, a U-tube is used with two small plugs of asbestos at the bend, the anode being in one limb and the kathode in the other. With this form of voltameter, even after the current has flowed for several days, no signs of iodine have been found in the limb containing the kathode. On account of the production of electric convection currents, the iodine voltameter does not seem to be quite so suitable for the accurate measurements of strong currents. After the current is stopped the zinc electrode is immediately removed, the solution stirred, and the amount of iodine liberated determined by titration with sodium thiosulphate. The author finds that a convenient strength of the thiosulphate solution is one in which one c.c. corresponds to the amount of iodine liberated by five coulombs of electricity. This solution contains 12·8375 grms. of pure recrystallised sodium thiosulphate per litre. It is possible to perform the titration to within 0·1 c.c., which corresponds to 0·5 coulomb, or, if the electrolysis lasts one hour, to 1/7200 ampere. In a comparison made with a silver voltameter, the current as deduced from the silver was 0·0264 ampere, and that deduced from the iodine 0·0266. The author considers that part of the difference may be due to the effect of oxygen dissolved in the solution of silver nitrate. Prof. Carey Foster considered this process for measuring currents a most valuable one. The idea of using a volumetric method for measuring currents was to him new. He did not, however, see the advantage of using a substance with a high electro-chemical equivalent if a volumetric method was going to be employed to estimate the quantity of the substance liberated. It would be possible to use a chloride, though in this case the titration would probably be less accurate. Prof. Silvanus Thompson said he thought the method would be very valuable, but he would like to know if any error was likely to arise if too great a current density was employed. The number the author had assumed for the atomic weight of silver (108) was only approximate; if the more accurate value (107·7) were used, the agreement between the results obtained with the silver and iodine voltameters would be improved. Mr. Trotter asked what was the largest current that could be accurately measured. Mr. Enright said he had used porous diaphragms in iodine voltameters, and found that the iodine collected in the positive compartment, while the water was driven over into the negative compartment. With strong currents it was possible to get almost pure iodine left in one compartment. Mr. Watson thought that, since the value for the electro-chemical equivalent of iodine used by the author was deduced from Rayleigh's value of the electro-chemical equivalent of silver, and that Rayleigh's experiments were performed in air, the difference obtained with the silver and iodine voltameters could hardly be due to the cause suggested. Mr. Elder warned the members that volumetric measurements were not so accurate or easy as they seemed. He particularly mistrusted a solution of sodium thiosulphate, since he had found a solution of this substance to change even in twenty-four hours. The difficulty of accurately reading the burette might be overcome by weighing the burette and its contents before and after the titration. The author in his reply said that with the size of electrodes he used (about 9 sq. cm. surface) 0·1 ampere was the maximum current it was safe to use. The only substance likely to be produced by too great a current density was periodate, which, since it was insoluble, would immediately be noticed. The influence of the dissolved oxygen was only appreciable with small currents where the electrolysis lasts some time, while in Rayleigh's experiments large currents were employed. The chairman, while returning thanks to the author for his paper, mentioned that in his experience he had found zinc salts to be very untrustworthy.—Mr. A. Sharp read a paper entitled a new method in harmonic analysis. The author, in this paper, applies the principle of the form of harmonic analysis for giving direct readings of the amplitude and epoch of the various constituent harmonic terms, previously described by him, to the performance of harmonic analysis without the use of an instrument. The kinematic principle is as follows: Let the curve to be analysed be drawn with a scale of abscissa such that the period is 2π. Let a wheel w roll on the paper and be connected with a tracing-point P in such a manner that as P moves uniformly in the x direction the axis of the wheel w turns uniformly counter clockwise in a horizontal plane, and the distance rolled through during any short interval is equal to the corresponding displacement of the tracer P in the y direction. The curve traced out by w the author calls the roller curve, and from the vector joining the initial and final points of this curve the amplitude and epoch can be determined. Suppose the periodic curve consists of a portion of the curve $y = a_0 + a_1x + a_2x^2 + \quad + a_mx^m$ repeated over and over again. Then, if the tracer is taken round this periodic curve you get a rolled curve which may be called the first rolled curve. If now the curve whose ordinates are $\frac{dy}{dx}$ is traced out, the roller curve obtained is the evolute of the first, and so on for $\frac{d^2y}{dx^2}$, &c. The author gives two worked examples, and compares the values of the coefficient obtained with those given by the harmonic analyses of the Guilds Central Technical College. Prof. Henrici said he had not received the paper in time to thoroughly master it, but he thought that, at any rate for curves where no discontinuity occurred, the relation found by the author between the roller curves was always true, the last evolute being a point, and the one before that a circle. The interesting point was whether the method was capable of being used for practical purposes, for it occupied a place with respect to harmonic analysis similar to that occupied by Simpson's rule in planimetry. Prof. Silvanus Thompson asked if the author had devised a form of mechanism capable of fulfilling the kinematical conditions given at the commencement of the paper. The author in his reply said he had devised such a mechanism, and that it was described in his previous paper. In addition he had since invented a more practicable form which he had patented. The chairman said the Society ought to congratulate itself on the large number of important papers dealing with harmonic analysis and planimetry that had lately been communicated.

Malacological Society, May 10.—Prof. G. B. Howes, President, in the chair.—On behalf of Miss de Burgh specimens were shown illustrating the variation of *Columbella mercatoria*, Linn.—Mr. Da Costa exhibited a collection of univalve mollusca from Lakes Tanganyika and Victoria Nyanza, and pointed out the entirely different characters of the molluscan fauna of these two lakes.—On behalf of Mr. C. S. Cox were exhibited living specimens of *Glandina* from Italy.—Mr. E. A. Smith exhibited an almost complete collection of the land and freshwater mollusca of St. Vincent, W.I. Mr. E. R. Sykes exhibited specimens of *Achatinella variabilis*, Newc, and allied forms, from the Island of Lanai. The following communications were read:—Notes on *Trochonanina* and other genera of the land mollusca, with reference to the animals of *Martensia Mozambicensis*, Pfr., and other species, by Lieut.-Colonel H. H. Godwin-Austen.—Report on the land and freshwater shells collected by Mr. H. H. Smith at St. Vincent, W.I., by E. A. Smith.—Note on the larval oyster, by M. F. Woodward.

Victoria Institute, May 6.—Dr. Chaplin in the chair.—A paper on the so-called *Pithecanthropus* of Dr. E. Dubois was read by Prof. E. Hull, LL.D., F.R.S., after which a paper by

Sir J. W. Dawson, C.M.G., F.R.S., on the physical character and affinities of the Gaunches, or extinct people of the Canary Islands, illustrated by photographs, was read. In it the author reviewed the historical facts as to the Canary Islands and these inhabitants, the characters of the crania found, and the weapons, ornaments, &c., and described the conclusions he had arrived at with reference to the relationship of the Gaunches to ancient peoples of Western Europe and Africa, and their possible connection with the colonisation of Eastern America.

Royal Microscopical Society, May 15.—Mr. A. D. Michael, President, in the chair.—Mr. J. Swift exhibited an improved form of the Nelson microscope-lamp, fitted with mechanical movements; and also a Wales microscope which had been fitted with the new mechanical stage.—Mr. T. Comber read a paper on the development of the young valve of *Trachyneis aspera*. The subject was illustrated with lantern photographs exhibited upon the screen.—Miss Ethel Sargant's paper, "On the first nuclear division in the pollen mother cells of *Lilium martagon*, &c.," was communicated by Dr. D. H. Scott.

PARIS.

Academy of Sciences, May 20.—M. Marey in the chair.—The decease of M. C. Ludwig, correspondent of the Medicine and Surgery Section, was announced by the President. M. Ludwig will be chiefly remembered for his work on blood pressures and circulation, on artificial circulation, and on the physiology of the nervous system.—Reduction to sea-level of the values observed for gravity at the surface of the earth (Coast and Geodetical Survey), by M. G. R. Putnam. A translation of some passages of this work is given by M. H. Faye, in which it is shown that Faye's correction causes anomalies to more nearly disappear than Bouguer's correction. M. Faye then discusses the probable form of the earth's crust, and shows the bearing of his discussion on the theories of geologists.—New researches on the thermochemical relations between aldehydes, alcohols, and acids, by MM. Berthelot and Rivals. A *résumé* is given of the known thermochemical data connecting aldehydes with corresponding alcohols and acids.—Existence of phosphorus in notable proportion in oysters, by MM. A. Chatin and A. Müntz. Not only has phosphorus been found in the shells of different kinds of oysters in the form of tricalcic phosphate, but organic phosphorus has been found in oyster flesh in quantity, more in Portuguese oysters (*Gryphea angulata*) than in French natives (*Ostrea edulis*).—Classification of the chemical elements, by M. Lecoq de Boisbaudran. A theoretical paper discussing the author's system of classification and the genesis of elements from a primordial matter.—On the spectroscopic analysis of gases obtained from various minerals, by Mr. Norman Lockyer.—On the reducing properties of sodium alcoholates at a high temperature, by MM. A. Haller and J. Minguin. The results of heating together in sealed tubes at about 200° C. are given for: desoxybenzoin and sodium ethylate in absolute alcohol; benzophenone and sodium ethylate; anthraquinone and sodium ethylate, amylate, and butylate respectively.—On stereoscopic projections and the "stereojumelle," by M. Moessard.—Studies on the activity of the diastole of the ventricles, on its mechanism, and its physiological and pathological applications. An abstract of a memoir by the author, M. Leon Germe.—A comparison between the spectra of the gases from cleveite and the spectrum of the solar atmosphere, by M. H. Deslandres. A list of wave-lengths of lines observed in the spectra of gases from cleveite is compared with a similar list of lines observed in the solar chromosphere spectrum (see p. 56). Twenty lines in the former list are recorded and thirteen lines in the latter list are shown to have the same wave-length, extending through the luminous and ultra-violet portions of the spectra. Two *permanent* chromosphere lines, 587·60 and 447·18, correspond to two of the principal gas lines, 587·60 (D_3) and 447·175. There now remain but two such chromosphere lines always obtainable, which do not correspond to lines obtained in terrestrial spectra.—On the isomeric transformations of mercury salts, by M. Raoul Varet. It is shown that black amorphous HgS disengages +0·24 Cal. in changing to the red amorphous variety, and yields a further +0·06 Cal. in becoming red crystalline HgS.—Action of nitrogen peroxide on the halogen salts of antimony, by M. V. Thomas.—Heats of formation of benzoyl chloride and toluyl chloride, by M. Paul Rivals. The substitution of the group (COCl) for a hydrogen in benzene or toluene results in an increase in the heat of formation of +58 Cal. and +55·3 Cal. respectively.—Study of senecionine and senecine, by MM. A. Grandval and H. Lajoux. Two alkaloids have been prepared from *Senecio vulgaris*. Senecionine appears to have the composition $C_{18}H_{26}NO_6$, and does not possess very marked reactions. Senecine appears to possess much more definite reactions with the usual alkaloid reagents.—On phenyl-sulpho-orthotoluidine and some of its derivatives, by M. Ch. Rabaut. In conclusion, attention is drawn to the resistance of this substance to oxidation and to its great stability in presence of dilute acids and heat, notwithstanding its amide character.—Analysis of a mummy bone, by M. Thezard.—On a leucomaine extracted from urine in cases of Angina pectoris, by M. A. B. Griffiths and C. Massey. A new poisonous base, causing death in two hours, of which the composition is given as $C_{10}H_9NO_4$.—On some improvements in the preparation and study of thin plates of sedimentary calcareous rocks, by M. Bleicher.—On the anomalous divisions of ferns, by M. Adrien Guébhard.—The catastrophes of Titel in the Banat and of Mendoza (Argentine Republic), by M. Ch. V. Zenger. Arguments are adduced to show a connection between these seismic phenomena and sun-spot appearances on the sun.—The use of crude petroleum for prevention of incrustations in boilers is advocated by M. G. Liévin.

BOOKS AND SERIALS RECEIVED.

BOOKS.—The Telephone Systems of the Continent of Europe: A. R Bennett (Longmans).—The Theory of Light: Prof. T. Preston, 2nd edition (Macmillan). Dental Microscopy: A. H. Smith (Dental Manufacturing Company).—A Reader's Guide to Contemporary Literature: W. S. Sonnenschein (Sonnenschein).—A First Book of Electricity and Magnetism: W. P. Maycock, 2nd edition (Whittaker).—The Way about Middlesex (Iliffe).—The Way about Hertfordshire (Iliffe).—An Elementary Treatise on Elliptic Functions: Prof. A. Cayley, 2nd edition (Bell).—La Pluie en Belgique: A. Lancaster, Premier Fasc. (Bruxelles, Hayez).—Nature in Acadie: H. K. Swann (Bale).—The Linacre Reports, Vol. 2: edited by Prof. E. Ray Lankester (Adlard).

SERIALS.—Botaniscbe Jahrbücher für Systematik, Pflanzengeschichte und Pflanzengeographie, Zwanzigster Band, 4 Heft (Leipzig, Engelmann).—Zeitschrift für Wissenschaftliche Zoologie, lix. Band, 2 Heft (Leipzig, Engelmann).—The Evergreen, Spring (Unwin).—American Naturalist, May (Philadelphia).—Papers read before the Engineering Society of the School of Practical Science, Toronto, No. 8, 1894–5 (Toronto).—Good Words, June (Isbister).—Sunday Magazine, June (Isbister).—Longman's Magazine, June (Longmans).—Chambers's Journal, June (Chambers).—Century Magazine, June (Unwin).—Journal of the College of Science, Imperial University, Japan, Vol. vii. Part 4 (Tōkyō).—Journal of the Institution of Electrical Engineers, No. 117 (Spon).

CONTENTS.

THURSDAY, JUNE 6, 1895.

THE "CHALLENGER" EXPEDITION AND THE FUTURE OF OCEANOGRAPHY.

The Voyage of H.M.S. "Challenger." A Summary of the Scientific Results. (With Appendices). Two Parts. (London: Eyre and Spottiswoode, 1895.)

THE two new volumes of the *Challenger* Expedition have appeared, and with them this momentous enterprise has arrived at its final close. It is well worth our while to seize this occasion for a few words of reflection on a scientific drama, which is equally great in all its parts and dimensions, as in the effects it has produced and will go on to produce, on the progress of a group of sciences which every day grow more important in their influence on human intellect and thought.

It is nowadays a very common complaint, that specialisation in scientific pursuits threatens to do away with that character of universality that was attributed in former times to all those who busied their brains with the phenomena of nature. I can fully remember how, in my own childhood, the naturalist κατ᾽ἐξοχήν found his example in Alexander von Humboldt. He was credited with "knowing everything," and whoever followed some small pursuit as a naturalist, partook, in a certain degree, of the prestige the great "Naturforscher" enjoyed in all circles of the reading public. When I was studying zoology at Jena, a fellow-student of divinity asked me once, "Please tell me what is the name of those stars?" "I don't know, my dear friend, I am studying biology." "Oh, I thought you 'Naturforscher' study all the natural sciences."

I am afraid we are at present drifting far away in the opposite direction, and the general public is rather inclined to believe that each naturalist or natural philosopher lives on an island, of which he investigates only a small corner, without caring a bit for the rest of the island, and still less for other islands and whole continents. Whether we are quite as bad, I will not try to decide; certainly those happy times are far behind us when a professor of mathematics and astronomy taught also physics and medicine, or when botany, zoology, and chemistry were represented by the only professor of medicine, and all these things were taught merely by books and traditions. But even those modest cases of personal union between zoology and botany, or between geology and zoology, which not unfrequently occurred in the first half of our century, have passed away now at its close. Instead of such personal unions, we meet with, in a well-equipped university, distinct chairs for zoology, comparative anatomy, embryology, palaeontology, geology, mineralogy; round each of these chairs we see gathering numbers of privatdocents and other teachers, who deliver lectures on distinct specialities of these sciences, which threaten to grow themselves again to independent divisions craving a chair for themselves. "Division of labour" is all very well; but if we do not in time prepare for better mental digestion and assimilation, the next century will live to see a new Babylonian turret; dispersion of languages will grow to such a degree, that even the inhabitants of the same scientific island will find it hard to talk to each other.

It is a consolation, under these circumstances, to see, that, along with division of labour, combination of labour takes its firm hold in the organisation of modern scientific life, and Moltke's maxim, "march separately, attack jointly," proves also useful in the peaceful battles of thought and science.

A splendid proof of this combination of labour lies before me in the numerous volumes of the *Challenger* Expedition. Physics, chemistry, geology, zoology, and botany, and all those nautical and hydrographical attainments of modern date, have combined to produce results which close a past of unwarranted belief, and open a future of new research, boundless in fertility of problems and of unknown possible effect on the human intellect and understanding.

The imagination of human kind from the beginning of historical ages, and along all its phases of development and evolution, took hold of those unknown regions of the heights of mountains as well as of the depths of the ocean. Covered by ice and snow, hidden in thick masses of clouds, out of which thunder and lightning and endless floods of rain and hail came forth, the ranges of mountains gave birth to the grandest and most appalling visions of powers, upon which the poor human individual looked aghast, against whose mighty influences he felt helpless, and whom he dreaded and revered. Every human being becomes a poet under the influence of fear and reverence. Both magnify and intensify impressions, even of the most common kind, and create combinations where the acutest observer could not discover any connection. Thus the oldest forms of religious belief, as well as the numerous forms of still existing superstitions, have peopled the tops of mountains and the depths of the seas with images of supernatural powers; the Olymp of Hellas, and the old German myths, the Hebrew Jehovah, and the rudest Paganism, found their abodes beyond the clouds, and below the waters. And who can resist the temptation of such dreams, grand and awful at once, when standing on those solitary heights of the Alps, with ice and snow, and rock and cloud around him and below him, and looking over endless ranges of peaks and valleys? Who is not struck by the image of death and destruction, when he wanders on the volcanic deserts of Etna, where there is not one leaf of grass, not one smallest insect to keep him company? And in the midst of the raging ocean, with waves dashing against the poor ship, and clouds spreading darkness around, who will refrain from images of terror created by the imagination of the boundless depths to which he has trusted his life? Will there ever come a time when the human mind replaces such emotions by the cool reflection that the minimum or the maximum of atmospheric currents and pressure causes the disturbance of equilibrium on the floods of the ocean to such a degree as to shake the balance of the floating mass of wood or iron, on which he happens to find himself, and bring its metacentre to a position which enables the water to supplant the air-filled spaces until the greater specific gravity of iron carries all away, through the lamina of the hydrosphere, down to the lithosphere, which resists further gravitational concurrence? And will ever barometer and thermometer, or the observing eye of the geologist, caught by phenomena of denudation or glacial erosion on Mont Blanc, diminish the trembling of

emotion when the eye measures the enormous distances it commands from such a height? Whoever has experienced the thrilling delight of that other emotion caused by insight and discovery; whoever knows that intellectual powers can produce as much enthusiasm as artistic and æsthetical emotion, will not be haunted by the sickening dread that human imagination could become stripped naked by the impious hand of science. Whoever cares more for the Why, than for the How, will gather around the temple of science; but those gifted natures, who are impressed by colours, shapes, and situations, why shall they not go on to shake their kaleidoscope of beauty and appearance, just as much as these go on drawing invisible threads of cause and effect between old and new facts?

Let us therefore not quarrel with the natural growth of the human mind, but rather accept in delight all such actions as include a great increase of knowledge in regions where ignorance lent the hand to superstition; and so let us hail the work of those who lifted a piece of the thick veil that covered the abyssal depths of the ocean.

It will always be one of the greatest of the many merits of the late Prof. W. B. Carpenter to have given the first suggestion to the *Challenger* Expedition. Not content with asking the Council of the Royal Society to throw in its authority with the British Government to undertake a new and complete course of research for the exploration of the deep sea, he entered into direct correspondence with the First Lord of the Admiralty, and carried his point so far as to receive the answer that the Government would be prepared to give the requisite aid in furtherance of such an expedition on receipt of a formal application from the Royal Society—in consequence of which answer the Royal Society at once proceeded to take these necessary steps; and after exchanging some correspondence with the Secretary of the Admiralty, the proposal to defray the expense of such an expedition out of the public funds was brought before Parliament and "received the cordial assent of the House of Commons" in April 1872.

It is to be lamented that in the "Narrative of the Cruise," neither the proposition of the British Government nor the debate of the House of Commons are reproduced literally. It would have been of high historical interest to the general, as well as to the special, reader to know exactly the wording in which the proposition was formed, and the views and opinions with which it was received. It is, perhaps, not possible to the editor of NATURE to supply even now this omission, but yet many in the outer world would greatly desire a reprint of the day's discussion which produced results so momentous as that great and memorable expedition of the *Challenger*. In uttering this regret, I can assure the British reader that, though a foreigner, I feel deeply my share of gratitude to both Government and Parliament of Great Britain. I cannot omit this occasion to congratulate science for having her wants so well interpreted, understood, and satisfied by all those who have a share in the *Challenger* Expedition, be it the Government or Parliament, be it the officers and crew of the ship, or the scientific staff and the authors of the voluminous reports lying before me.

And I may be permitted to claim some personal license to proffer my thanks in the name of science, and especially of biological science; for at the time when Dr. Carpenter and the Royal Society asked the British Government to undertake the expedition, I was myself engaged in a collateral enterprise of similar tendency, and felt the same necessity to ask for help and assistance of the authorities of the German Government, and, in smaller degree, of the Governments of almost all civilised States and nations. A few years after the British House of Commons had "cordially assented" to the proposition of the Royal Society, and voted the funds demanded by the Admiralty, the German Reichstag passed a resolution, based on a petition of Helmholtz, Dubois-Reymond and Virchow, by which the Government of the empire was asked to grant an annual subvention of £1500 to the Zoological Station of Naples, a subvention not only continued up to this date, but four years since increased to £2000. These votes of the two great parliamentary bodies go far to disprove the old doctrine, that science and the promotion of research are to be abandoned to private enterprise, and to the favours they may meet with accidentally in raising money by public subscription, or falling in with wealthy private persons whose interest and generosity can be won over. I am afraid, if the House of Commons had not granted the necessary funds, the *Challenger* Expedition would never have taken place, and our ignorance about the many great and innumerable smaller questions connected with the deep-sea problems would be still the same as in 1872. Had not the German Reichstag voted in favour of the Zoological Station, all my personal efforts would have failed, and neither the Naples Station nor the Plymouth Laboratory, nor, perhaps, the many other imitations of "the big brother at Naples," would have had the chances with which they have met now. No; let science not be immodest and ask for all and everything from the State; but let it still less linger on and wait for the chances, growing always scarcer and scarcer, of being endowed by private source, be it public subscription or donation from wealthy men and amateurs. The number of persons combining great wealth with sufficient culture is unfortunately not on the increase; inherited wealth, which offers more chance for the acquirement of higher intellectual pursuits, is decidedly diminishing. The demand for funds for the endowment of research is doubtlessly augmenting, and the competition in the advancement of science is such, that the nation which is not ready to pay its share, will either be thrown in the background, or live like a parasite on the intellectual blood of its neighbours. How long such a parasitic existence could be protracted, remains to be seen; but certainly no great nation will deliberately accept such a disgraceful situation, the more since it cannot be doubted that each nation has its peculiar gifts and talents, which make its co-operation indispensable in the chorus of other nations and in the interest of humanity. It must be granted, that the weight of a nation in the scale of culture depends on the power and number of men of genius it has produced and goes on to produce; it may also be granted, that a genius has been known to open up his own ways and make his career through all the adversities of fate. Yet a genius needs to feed quite as much, or perhaps more than an ordinary mortal, and some think it would be economical

to give him at least average chance. Would any genius have been capable of diving, on his own account, to the great depths of the Pacific? or would a genius find it possible to replace, by his own work, the ant-like activity of the Naples Station? Hardly. But let him come now and handle the innumerable data of the *Challenger's* investigations, or use the opportunities offered by a modern laboratory to give us a solution of the problem of heredity, or decide whether natural selection suffices to account for the evolution of the organic world, or whether other principles must be sought. The genius of Pasteur and Lister and Koch have opened the enormous field of research regarding the nature and effect of bacteria, and I think the world has not been the worse for France and Germany spending public money for the equipment of large laboratories to enable those geniuses to continue, in the most effective way, their labours.

Certainly not every whim or fancy of a learned individual can be accepted as a sufficient reason for spending public funds; some sort of a controlling apparatus will always be necessary. But in the Royal Societies, National Academies, and other learned bodies of high standard, each nation has already what is wanted, and it is understood well enough that such bodies are often even more difficult to be won over by some new rising genius than a Minister of Public Instruction or the outside public. It is, therefore, not to be anticipated that from the Scylla of nihilism in officially supporting research, one must necessarily glide down into the Charybdis of supporting whatever scheme comes out of the fervid brain of a young discoverer. But this much can be said, or repeated over and over again—for it is certainly no new truth—that the mental and intellectual productions of a nation ought not to be the last, nor the least, in their claims on the public money; and it may be maintained with all confidence, that hardly any other expense will so amply repay the budget of a nation, both materially and ideally, as the funds handed over for the promotion of research, or, in the truer expression, for the *organisation* of research.

For it is in this, that the real future lies: in organisation. Being organised, the small Japanese empire was more than a match to the tenfold bigger Chinese mass: being organised, a few British regiments can keep populations in abeyance, which, if they were equally well organised, might crush them in a moment. And to be organised, even in the intellectual sphere, means to economise natural powers and not throw away chances, which if they cannot perhaps be brought about deliberately, nevertheless can be profited by when they occur—and they occur always and everywhere.

Organisation of research, will, I do not doubt, become the special feature of the coming century. It would be well worth to provoke discussion about schemes, ways and channels, into which organised research ought to grow. Each nation may adopt its own, according to its character, habits, and prejudices. But one feature ought to be observed with them all, for it will soon become uppermost; that is, *international organisation* of those interests and productions by which all the nations may be benefited together, without being forced to arrange separately, each for itself, what more effectually and with less material and intellectual effort can be provided for all of them at once. And there can be no doubt that foremost, in this regard, stands the question: *How to reorganise, or organise at all, scientific publication?*

It cannot be doubted that the way in which we deliver over to publicity at present the results of the work of hundreds and thousands of investigators, is all but destitute of any regulating principle. Publishing in the nineteenth century resembles very much the kind of warfare practised in bygone times, when regiments were the property of single individuals, who were responsible for their equipments, nourishment, efficiency, and who entered into contracts with their men and soldiers and with states and princes. Defection on the one side, plundering on the other, were concomitant features of such arrangements, which one only need compare with the present constitution of the Prussian army to feel at once what powerful element organisation has proved to be. Why shall the most subtle of human activities, the mental and intellectual functions, not be liable to profit in the same degree by organisation? Why shall prejudice and egoism be permitted to govern with almost absolute sovereignty in the lofty regions of thought and speculation, of experiment and observation—in one word, of research? Organisation is not pedantry, discipline not slavery, genius no direct contradiction to order and measure. Originality and individualism will neither be sacrificed nor diminished, if certain rules are observed in bringing the results of investigation to public knowledge, and a better, more economical, and more effective system of reporting and recording is adopted, with the intention to facilitate the communication of valuable scientific results over the greatest possible circles of competent readers. It is true that the all-powerful *vis inertiæ* will go far in opposing any serious attempt of reorganisation in this department; but, as I remarked at the commencement of this article, unless we put hands and shoulders to the work, we shall unavoidably arrive soon at a state of chaotic confusion, where the worse elements may be conspicuous, and valuable productions at times be choked among mediocrity.

It would lead me too far away from the direct subject of this article to develop here any scheme of better arrangement for scientific publication; and if I am not mistaken, the feeling that such arrangements ought to be found and to be universally introduced, is spreading rapidly among competent and conscientious men of science. Let these soon unite and form national and international centres for the organisation of scientific publication—a more wholesome influence on the progress of science and research can hardly be imagined nowadays.

The two new and last volumes of the "*Challenger* Report" are the work of Mr. Murray, the true soul of the expedition, to whom science owes a great debt of gratitude for his never-ceasing care and toil, and for his talent and amiability, with which he undertook the great burden of superintending the publications of the expedition, besides himself adding most remarkably to the vast amount of new knowledge regarding the deep sea.

In the "Editorial Notes" to these two volumes, Mr. Murray has some paragraphs on the whole expedition so characteristic that I think it right to repeat them here to every reader who does not happen to lay his hands on the volumes themselves. Mr. Murray, after having given

an account of how in general the collections and the reports on them were disposed, adds the following :

"From beginning to end the history of the *Challenger* Expedition is simply a record of continuous and diligent work. There were few opportunities for brilliant exploits during the voyage. The daily and hourly magnetic and meteorologic observations, the handling of the ship during the tedious deep-sea investigations, the work connected with the boat excursions and expeditions on land, in addition to the usual operations of the marine surveyor and navigator, all demanded from the naval officers and seamen an amount of care and attention far surpassing what is required during an ordinary commission of one of Her Majesty's ships. The labour connected with preserving, cataloguing, and packing the biological and other collections on board ship was enormous, so also was that involved in their subsequent examination on the return of the expedition and their distribution to specialists in many parts of the world. All this was, however, accomplished with success, and the typical collections have now been deposited without any mishap in the British Museum. The majority of the authors of the special memoirs have spent years in the examination of the collections and in the preparation of their manuscript and illustrations for the press, without other remuneration than either a copy of the *Challenger* publications or a small honorarium to cover the outlay necessitated by their researches. The payments of the civilian staff have been very moderate, and in my own case, at least, have not covered actual expenditure in connection with the work of the expedition.

"The great difficulty in carrying through an undertaking of this nature arises from considerations of time. The researches of the specialist tend ever to become more elaborate : in no case were the authors of the larger special reports able to terminate their work within the original estimates as to time and bulk. The limitations in reference to expenditure imposed on me by the Government often rendered it imperative to curtail the investigations, and to cut out matter from the memoirs when, in other circumstances, I would gladly have fallen in with the views of contributors and collaborators. The researches and publications connected with the expedition might have been extended in several directions with advantage to science had the allotted time and funds permitted ; as it is, a few collections have not been thoroughly examined, and some observations have not been fully discussed.

"In June, 1872, I was appointed one of the naturalists of the *Challenger* when the expedition was being fitted out. During the past twenty-three years my time has been wholly taken up with the work of the expedition and in the study of those subjects which the expedition was organised to investigate. The direction of the whole of the work connected with the publication of the scientific results passed unexpectedly into my hands, and I have done my best in the circumstances to place on permanent record a trustworthy account of the labours of this famous expedition. It has been my earnest endeavour to complete the publications in a manner worthy of the naval position and scientific reputation of this great empire. Notwithstanding the troubles, personal sacrifices and regrets necessarily connected with the work, it has been a pleasure and an honour to have taken part in explorations and researches which mark the greatest advance in the knowledge of our planet since the celebrated geographical discoveries of the fifteenth and sixteenth centuries."

It is hardly possible to speak in a more truthful, simple, and dignified manner of one's life's work than here Mr. Murray speaks of the work and the difficulties that beset the *Challenger* Expedition, "cujus pars magna fuit." He might have used quite other language, and have felt sure to meet the full acknowledgment of his contemporaries, and nobody will certainly dispute him the proud sentence with which he finishes the above account. There can hardly be any doubt about the epoch-making importance of the *Challenger* expedition, and if in the first letter of Dr. Carpenter to the Royal Society attention is drawn to an article in this journal (NATURE, vol. iv. p. 107, 1871), in which it was stated that the Governments of Germany, Sweden, and the United States were preparing to dispatch ships to various parts of the ocean, expressly fitted for deep-sea exploration, and the question put forward, whether Great Britain should not step in to do her share in such work, I think it might well be urged now, after Great Britain having done her work in the most unparalleled way, that other nations might continue and profit by the experience of the *Challenger*. Such expeditions may be undertaken by deliberately dividing the task of filling the gaps and lacunes left by the *Challenger*, one nation taking the Atlantic, the other the Indian, a third the Pacific, and a fourth especially the Antarctic Sea for its investigation and exploration. A large basis has been laid by the *Challenger*, capable of bearing any superstructure to be erected on it. Let France and Germany, the United States and Russia take up this work after a mutual understanding, let Sweden or Norway explore once more the North Polar Sea, Italy the Red Sea, and let international organisation add a second chapter to oceanography, after the first has been so well worked out by Great Britain.

Nevertheless, whatever important results may be arrived at by such repeated expeditions, embodying both principles—division of labour and combination of results—the future of oceanography requires still other means of research. Whenever a new domain of science is opened up, either by the isolated work of a discovering genius, such as Pasteur and Koch, or by combination of rarely found chances, such as the *Challenger* Expedition offered, the immediate consequence is that specialisation sets in to work out all the different chapters of the new doctrine, enlarging the basis, multiplying the parts, drawing new conclusions, correcting old ones—in short, bringing about a detailed colonisation of the newly-discovered intellectual areas. But no oceanic or African colony can live and prosper nowadays without well-established communication with its motherland ; no haphazard visits of travellers can supplant the permanent and systematic exploitation that alone provides those conditions of life which make a colony prosper. And the same holds good for intellectual colonising, and especially for problems of oceanography.

If we look over the fifty volumes of the "*Challenger* Reports," we see, at once, that the lion's share belongs to biology. More than nine-tenths of them are purely biological, and almost all the others include some important biological elements. It is therefore hardly wrong to suppose that the future of oceanography will lie with biology, and with its ways and means for increasing our knowledge. The problems of biology, of course, are extremely varied, and many of them may be studied in every inland university. Not so the problems of marine biology, for which the last twenty years have established

the utter necessity of laboratories near the sea-shore. Here we are only in the beginning of a movement, which will go far to increase our knowledge of the conditions of marine life.

If the establishment of marine laboratories on different parts of the Mediterranean and on both sides of the Atlantic—not to speak of the North Sea and the Baltic—have proved a necessity: if already, both in Japan and in California, the coasts of the Pacific have been provided with such scientific outposts, it cannot fail that, by-and-by, Africa, Australia, and the Polynesian Archipelago will also have their biological stations. It is a great pleasure to me to be able to state here, that a small beginning is being made at Ralum in Neu Pommern (alias New Britain), the neighbour island of New Guinea, from whence numerous specimens of *Nautilus pompilius* have lately been procured. An intelligent and enthusiastic German planter, Mr. Parkinson, living since many years on that island, visited me a year ago in Naples, and offered spontaneously his help and services to establish a small station on his own land. According to his views, locality and climate will favour such a plan, and as there is every six weeks a steamer of the North German Lloyd from Ralum to Singapore, and soon perhaps another one to Sydney, the possibilities of a tropical archipelago station are given. The Naples Station has undertaken to provide the scientific equipment of its infant brother at the Antipodes, and my friend Major Alex. Henry Davis, from Syracuse (New York), who, already helped so much to establish lasting and fruitful relations between the United States and the Naples Station, has again stepped forward to provide for the first pecuniary wants of the Papua Station. Let us hope that this small beginning will reap some fruits, and the more so, as Mr. Arthur Willey, well known by his work on the development and morphology of the Tunicates and Amphioxus, has gone there as first pioneer of biology to study the development of *Nautilus pompilius*. His impressions have been as yet very favourable, and he thinks that the fauna of New Britain will amply repay every sacrifice of Mr. Parkinson and Major Davis. If the local authorities of New South Wales, or Victoria, or New Zealand, would find it worth their while to help to a laboratory in Port Jackson, or somewhere else in Australia: if in the Cape Colony somebody would do as Mr. Parkinson has done—numerous problems thrown open by the work of the *Challenger* would make progress, and the threads of biological study would draw nearer and nearer to encircle the most distant parts of the oceans.

But the greatest stroke would come, if one nation or an international combination would present biology and oceanography with a steamer, expressly built for purposes of such research as the *Challenger* performed. In the year 1884, I attempted something of the kind by forming a committee of influential men in Germany for the purpose of collecting £15,000 to £20,000, with which to build a yacht large enough to go round the globe, and serving as a floating biological laboratory. Of course it was not the sum of money wanted for the construction of such a ship which constituted the main difficulty of the scheme, though I failed even in that from reasons which had nothing to do with the scheme itself. The true difficulties lie in the extraordinary great regular expenses in commissioning such a ship, as every owner of an ocean yacht understands. Of course I was also prepared for that, and have no doubt that my plans would have answered, at least to some extent, but I was compelled to recognise the truth of the old proverb, "qui trop embrasse mal étreint." I do not know whether I shall yet be able to return to the attack; it seems rather unlikely, but it is my firm conviction that this scheme is, if not the only one which will permit us to conquer the battlefield, at any rate the chief means to enlarge our knowledge in oceanography, and will and must therefore be executed in no distant future.

Such a ship ought not to be continuously crossing the oceans: on the contrary, its best services would be rendered by giving it the chance to thoroughly investigate distant areas for distinct problems. Give such a ship the commission to study in the greatest possible detail, and in a comparative way, life and formation of the coral reefs in the Indian Ocean; let it be stationary for months together on the most favourable spots for such a study; prepare a scientific staff of specialists for the work, land them where the best opportunities for a transient establishment of a small laboratory is to be got, assist them by as many hands of the crew as can be spared, help them by the steam-pinnace on board, use the diving dress as well as native divers, and study for hours under water the construction and the destruction of the reef, apply all kinds of dredging and surface-fishing at day and night, have well-trained laboratory servants for the preservation alive and in alcohol of such organisms as are required for further study,—in short, do as if a well-appointed laboratory were transported to Polynesia; and be sure that results will ensue which by no other contrivances can possibly be obtained, especially if the ship be under no restrictions, and can stay in any one spot as long as may be requisite.

For it is the great drawback of the usual men-of-war expeditions, that they are only allowed a few days or weeks to remain at the same locality. There are so many other objects, to which it is necessary to give full attention, that they are always driven away from the work when the preliminary difficulties are just overcome. Science must be sovereign on board, the scientific leader must be absolute for determining the course to take and the time to remain. Discipline on board the ship must, of course, be handled by the captain or his officers, but the general dispositions of the work must remain with the scientific leader. That alone already would make a great difference in such an expedition from all those antecedent, and though very often the naval captains of expeditions for scientific purposes might well enough be transformed also into scientific leaders, nevertheless they are dependent on orders from home, and cannot always understand the importance of embryological, physiological, or other specialist work, for which they have to stay a month or two longer in the same harbour.

Again, the scientific staff must be selected with greatest care in regard to technical and personal accomplishments. If the staff is not varied enough, and does not include men of different attainments, many opportunities for investigation must be lost for want of previous knowledge on the side of the naturalists on board. On the other hand, nothing is more difficult than to live together for months,

or even years, on board a ship, for men not well trained to such existence, except where the composition of the staff is made with a sharp eye for compatibility and incompatibility of character. Especially the scientific leader must be a man of imposing personality rather than of special scientific competence, for it will fall to his share to dictate in every case where conflicting tendencies threaten to do away with social harmony.

But though all this may be considered to offer considerable difficulties in the way of execution, nevertheless the future for oceanography will belong to such floating biological stations, and the time is perhaps not so far distant, when more than one of them will cross the oceans, and supersede completely the now adopted system of single-handed expeditions of young naturalists. The necessity for such expeditions is doubtless existing, in so far as it is better to try the solution of problems regarding the tropics by travelling alone than by staying at home. And no doubt very many geographical, ethnographical, geological problems have been greatly advanced by competent travellers, and will furthermore be advanced in the same way. Collections of animals and plants have been made, mostly terrestrial, and the systematic part of biology has had its due share. But all more complicated studies, such as require more technical appliances and preparations, remain in the background, for the same reason which has forced us already in Europe to establish well-organised morphological, physiological and chemical laboratories, both inland and on the sea-shore. And if we cannot go on without them in Europe, where the general conditions for biological research are so much more advantageous, we must certainly have them, if we wish to advance our knowledge of tropical, terrestrial and marine organisms.

Botany enjoys already some advantages through the botanical gardens in Ceylon and Java, and it is to be hoped that the British and the Dutch authorities will use their exceptional opportunities in both places to establish some sort of regulations for their use by the botanists of all nations. May it not be possible to enlarge these botanical gardens by adding also some facilities for research of animal morphology? The Zoological Station at Naples has a special part prepared and equipped for morphological and physiological botany; in the first place, of course, for marine algæ, but any other sort of botanical study, for which Naples offers opportunities, might be undertaken there, and already a valuable work on the cultivation of figs has been greatly assisted by the Zoological Station. No doubt every naturalist who travels in Ceylon or the Sunda Archipelago receives the most valuable advice and assistance by Messrs. Trimen and Treub, and perhaps these most competent gentlemen would be the first to advocate a larger endowment of their establishments in the sense just now indicated; science and research would be certainly greatly benefited by it.

All these dreams and perspectives are opened up before us when we are looking over the enormous mass of new facts and new material for study brought together by the *Challenger*. And to think that there were only four naturalists and one chemist on board all the years long, and one of the naturalists died during the expedition! It is, I think, only right to remember here that two others of the gentlemen of the civilian staff so heavily overtaxed their strength with the often surely very monotonous, and always very hard work, that their health broke down soon after their return, and they fell victims to their enthusiasm. If it is only right to pay the highest possible respect to Mr. Murray for his extraordinary power of work, talent for administration and competence in dealing with the special problems of deep-sea deposits, and if we gladly recognise the excellent work done by Mr. Buchanan, I think nobody will be so ready as these two gentlemen to join here in thankful remembrance of the share of work that fell to their late companions, Sir Wyville Thomson, Prof. Moseley, and Dr. von Willemöes-Suhm. And may it be once more permitted to the writer of these lines, who by right or wrong claims some special title for it as a sort of international official of biological science, to utter the thanks of science to the officers and men of the *Challenger*, and to the Admiralty, and to the British Government and Parliament, and to the whole British nation for having set the example to the world of one of the grandest and most successful scientific expeditions that ever has been, and most likely for considerable time to come will be, started.

ANTON DOHRN.

OUR BOOK SHELF.

Horses, Asses, Zebras, Mules, and Mule Breeding. By W. B. Tegetmeier, F.Z.S., and C. L. Sutherland, F.Z.S. (London: Horace Cox, 1895.)

THE first portion of the title of this interesting work is somewhat misleading, for with the exception of some half-dozen pages which deal mainly with the distinctions between the horse and the other species of the genus, and a description of the supposed new species known as Prejevalsky's Horse, the book entirely relates to asses, zebras, and mules. None of the varieties of the horse which have been produced during the period of its long domestication are referred to. We mention this fact in case the general reader should infer from the title of the work that it was a treatise on the multitudinous domestic varieties of the horse which exist in nearly every quarter of the globe.

The volume is conveniently divided into two parts. Part i. is chiefly of zoological interest, and contains very complete and accurate descriptions of the existing species of the genus known to modern zoologists under the name of Equus, including, in addition to Prejevalsky's Horse, an account of the still more recently discovered Grevy's Zebra. The engravings which illustrate the letterpress are particularly good, and will greatly assist the student in his endeavour to master the peculiarities of each species. It concludes with a chapter on the hybrids which may be produced by crossing the horse with the other species of the genus Equus.

Attention should be directed to an assertion on the part of the authors that a remarkable and noticeable difference exists in the period of gestation of the mare and ass. The duration of gestation in the mare is well known to be eleven months, and it has generally been assumed that it was similar in the ass and zebra. The authors, however, emphatically assert that in asses and zebras it usually exceeds twelve months; one of them, Mr. Sutherland, who is well known as an extensive breeder of mules, quotes from his stud-book eight instances of the period of gestation in the ass, the result in six cases of a single service, the period varying from 358 to 385 days. It seems strange that such a marked difference should have hitherto escaped mention in all previously published works.

Part ii. is devoted exclusively to mules and mule breeding, and is replete with valuable and exhaustive information on these subjects. The authors strenuously deny the existence of fertility in either the male or female mule, affirming that abnormal lactation not unfrequently occurs in female mules, when milk is secreted in great abundance, and that the foals which they are observed to be suckling are in reality the foals of other animals which the mules have adopted. With regard to the oft-quoted instance of a mule in the Acclimitisation Gardens in Paris, which has produced foals when mated both with the horse and ass, the writers doubt whether the animal is a mule, and assume that she is an ordinary mare, whose female parent was influenced by a first alliance, as is so often the case in dogs and other animals. If their contention is correct, the mule may still aptly be described as "an animal of no ancestry and with no hope of posterity."

The writers are enthusiastic, nay even fulsome in their praise of this hybrid, and bitterly lament the lack of appreciation in which it is held in Great Britain as compared with America and some European States. "In endurance," say the authors, "capability of hard labour, economy in keep, longevity, and freedom from disease, mules far surpass horses." Into so controversial a matter this is not the place to enter, and we must content ourselves with the belief that so plain and oftentimes so ugly an animal as the mule will never supplant to any great extent, in this country at least, the beautiful and graceful varieties of the horse of which Englishmen are naturally so proud.

To any of our readers who are interested in the subject of mule breeding, this work may be heartily recommended; and, in conclusion, we feel bound to compliment in the highest terms all who have been instrumental in its production. W. F. G.

The Moon. By T. Gwyn Elger, F.R.A.S. Pp. 174. London: George Philip and Son, 1895.

IN this latest work on the moon, from the pen of one of the foremost of British selenographers, the most noteworthy feature is the excellent chart, eighteen inches in diameter; this is given in four quadrants, but it can also be obtained complete and separately. All the named formations are distinctly shown, and the names of the more important are very clearly printed on the map itself. The greater part of the text resolves itself into a descriptive index to the map; but though this appears in rather stereotyped fashion, it embodies a good deal of information which has been gleaned by the author during many years of observation. An introduction of forty pages deals with lunar phenomena generally, and includes numerous hints which will be of use to the observer. Mr. Elger objects most emphatically to our satellite being spoken of as a changeless world, and justifies his position by stating that volcanic outbursts, producing mountains as large as the Monte Nuovo, might occur in many parts of the moon without the world being any the wiser. Though possessing little of novelty, and not appealing to the general reader, the book and map together constitute a handy work of reference which observers of experience, as well as beginners, will be glad to have by them. A few details as to the phenomena to be observed during eclipses of the moon, might have been included with advantage.

Algebra. Part i. By M. H. Senior. Oldham: D. W. Bardsley.

KINDERGARTEN methods of teaching are now applied to most subjects. In this small book of fifty pages, the author endeavours to make algebra interesting to young students by associating the abstract symbols with concrete objects. The novel features of the book are the explanation of brackets, the exercises on factors, short methods of multiplication and division, the elucidation of signs, and the numerous practical examples.

LETTERS TO THE EDITOR.

Argon and Dissociation.

THE discovery of the new substance argon, by Lord Rayleigh, has given rise to a difficulty which, it is thought by some, shows that the periodic law of Mendelejeff has not that generality which has been attached to it by chemists during the last few years.

According to Lord Rayleigh's determination, the density of argon is 19·9 ($H=1$), making the atomic weight 39·8, as the molecules are shown to have no internal energy of the same order as their energy of translation, and hence to be monatomic. Argon with this atomic weight cannot possibly find a place in the natural classification. If its atomic weight were less than 39·1 (the atomic weight of potassium), argon would fall in the VIIIth or interperiodic group in Lothar Meyer's table; and its properties, so far as they have been investigated, would harmonise with this position.

The determination of the vapour density of iodine by V. Meyer, Crafts and Meier, and others, has shown that at temperatures below 1000° C. the gas consists of diatomic molecules, while above this dissociation takes place, and above 1500° C. we have the dissociation complete, and the molecules are monatomic.

Why, then, cannot we have a similar behaviour in the case of argon?

If argon at low temperatures (somewhere near its critical point) consisted of diatomic molecules, which dissociate as the temperature rises, the difficulty of the position of argon would be removed. Thus, suppose at the temperature at which 19·9 was determined as the density of argon, the dissociation has proceeded so far that 5 per cent. of the molecules remain diatomic; the average molecular weight would be 39·8, but we should have two kinds of molecules, monatomic and diatomic, and the atomic weight under these supposed conditions would be

$$\frac{39{\cdot}8 \times 100}{105} = 37{\cdot}9.$$

The ratio of the specific heats, at constant pressure and constant volume, taking 1·4 for this ratio for a gas with diatomic molecules, and $\frac{5}{3}$ for a gas with monatomic molecules, would be for argon, on the above supposition,

$$\frac{95 \times \frac{5}{3} + 5 \times 1{\cdot}4}{100} = 1{\cdot}65.$$

This value agrees very well with the values (1–16 1–65) determined for argon.

This explanation reconciles argon with the natural classification; and as yet no facts have been published in opposition to it.

If this hypothesis be true it could be easily verified, for at temperatures, not much higher than that at which the vapour density determinations were made, the dissociation would be complete; and hence the vapour density in agreement with a molecular weight about 38; and also at lower temperatures than that at which the vapour density has been determined the gas would not obey Charles' law: for the recombination of the single atoms to form diatomic molecules, and possibly molecules containing a greater number of atoms, would cause a contraction greater than that due merely to the cooling of the gas according to the ordinary law. PENRY VAUGHAN BEVAN.

Melbourne University, April 18.

PROF. BEVAN ascribes to me work done conjointly with Prof. Ramsay. An addendum to our paper (see *Proc. Roy. Soc.*) contains our account of experiments by Prof. Ramsay, especially directed to examine the question raised.

It has turned out that the gas possesses the same value of $\frac{pv}{T}$ as hydrogen, and that the value of this expression is not altered between − 90 and + 250°. The most trustworthy determination of the ratio of specific heats gives the number 1·65; but much dependence is not to be placed on the accurate value

the second decimal. Very concordant determinations of density gave as a mean number 10·00.

Argon, therefore, shows no sign of association on cooling, nor dissociation on heating, as Prof. Bevan thinks it might.

RAYLEIGH.

Terrestrial Helium (?).

PROF. PASCHEN and I have lately made a careful determination of the wave-length of the strong yellow line emitted by cleveite when heated in a Plucker tube. We owe the mineral to the kindness of Prof. Rinne. My large Rowland concave grating of 0·5 metre radius, clearly shows the yellow line to be double. Its less refrangible component is much weaker, but comes out quite bright, when the stronger one is brilliant. We photographed the two lines together with the second order of the spark spectrum of iron. There are a number of iron lines on each side that are included in Rowland's list of standard wave-lengths (*Phil. Mag.*, July 1893). From these we interpolated the wave-lengths of the yellow lines by micrometric measurement. Three different plates taken on different days gave us:

Strong component.		Weak component.
5875·894	... .	5876·210
5875·874	... .	5876·206
5875·880	... ...	5876·196
Mean 5875·883		Mean 5876·205

We think an error of more than 0·025 very improbable.

Now Rowland's determination of D_3 (*Phil. Mag.*, July 1893) is

5875·982

the result of three series of measurements which he believes to be accurate to 0·02.

The difference between this value and the wave-length of the strong component is much too large to be accounted for by an error of observation.

We do not therefore agree with the conclusion, drawn by Mr. Crookes, that the unknown element helium causing the line D_3 to appear in the solar spectrum is identical with the gas in cleveite, unless D_3 is shown to be double. Perhaps Prof. Rowland will tell us if this might have escaped his notice. From his note on D_3 in *Phil. Mag.*, July 1893, it appears that D_3 cannot have been so wide as to include both lines, because he would then not have considered his determination accurate to 0·02. As for dispersion, we may see in his table of solar spectrum wave lengths that he has frequently measured three and even four lines in an interval as large as the one between the components.

Hannover Techn. Hochschule, May 10. C. RUNGE.

The Origin of the Cultivated Cineraria.

I HAD hoped that it would not be necessary for me to say anything more upon this subject. But Mr. Bateson's last letter seems to require a few remarks on my part.

I confess that I find it very difficult to follow his train of arguments. All I can do is to restate once more my original position, and endeavour to see how far Mr. Bateson has been successful in impugning it. I am sorry that Mr. Bateson thinks I have "treated" him "to some hard words," though I confess he seems to me, in that matter, quite able to take care of himself.

I asserted then (*a*) that the cultivated Cineraria only differs from the wild form, putting colour changes aside, in dimensional differences. I believe that in saying this I am expressing the deliberate opinion of the Kew staff, the members of which [illegible] would have no hesitation in dis[illegible] their chief, if they thought otherwise. To this [illegible] I [illegible] that Mr. Bateson advances any serious [illegible]

[illegible] (*b*) I assert [illegible] that these dimensional differences had [illegible]. To this I understand Mr. Bateson [illegible], [illegible] I [illegible] that he has brought forward a [illegible] of [illegible] the contrary.

[illegible] Mr. [illegible] position. He asserts, in common [illegible] that the modern Cineraria is of hybrid [illegible] conclusion. And here I [illegible] Dr. Masters, F.R.S., the well-known [illegible] of the *Gardeners' Chronicle*, who in that paper for [illegible] 21, 1881, [illegible] "Cinerarias and Pelargoniums,

again, which originate from one species, vary from seed but not from buds; and the same may be said of the Cineraria, the offspring of one species."

Mr. Bateson complains that I do not give "any specific answer" to the historical evidence. I thought I had made it sufficiently clear in my last letter that: (*a*) I doubted its value for scientific purposes: (*b*) I set it aside as irrelevant on account of the impossibility of proving the descent of the modern Cineraria from its supposed ancestors. Both Prof. Weldon and I have shown that the historical evidence can be handled both ways. But I prefer to set it aside altogether in the face of objective facts.

Mr. Bateson's next step is one to which I most seriously demur. He transforms a proposition of mine into terms to which I could not assent, and then proceeds to attack it. He makes me say that "to improve a plant the only safe way is by selecting," &c. I absolutely never said anything of the kind. "Improve" in horticulture is a word of large connotation. I confined myself to the production of dimensional changes, and I believe that what I said was in accordance with horticultural experience.

To demolish my position, Mr. Bateson has to get over the fact, which seems to me incontestable, that there is no essential morphological difference between the cultivated Cineraria and the wild *C. cruenta*. To do this he trots out the Himalayan rabbit. I cannot but admire his courage. What possible analogy can there be in the two cases? Two "breeds" of rabbits are crossed and produce a third *different from either*. If the modern Cineraria is of hybrid origin, then it has eliminated traces of all but one of its parents. The principle of economy of hypothesis makes me slow to believe this. Anyhow the Cineraria has clearly not produced anything analogous to a Himalayan rabbit which differs from both its parents.

As to Mr. Darwin's account of the origin of the Cineraria, I must frankly take the responsibility. I have no doubt he worked with ordinary garden kinds. He wrote to me for information as to their origin. At the time I was entirely ignorant of the subject. I wrote to Mr. Thomas Moore, who was considered the best authority on such matters, and he sent me the traditional account. I passed it on to Mr. Darwin, with the opinion, no doubt, that I thought the information trustworthy. So I am afraid Mr. Bateson is only appealing in this case from Philip sober to Philip drunk; *i.e.* from my own considered opinion to my unconsidered one.

I will now wind up all I have to say on the subject with a few miscellaneous remarks.

There can be no two opinions as to the importance of the study, from the point of view of organic evolution, of the changes which can be brought about in plants under cultivation. But it must be conducted with scientific precision. This discussion will not have been fruitless if it directs attention to the subject. A beginning has already been made. M. Bornet has worked on the genus *Cistus* at Antibes, and has reconstructed some of the forms, as to the origin of which there was only "historical evidence," described and figured by Sweet. My friend Count Solms-Laubach is engaged on the cultivated forms of *Fuchsia*, and I am quite sure that any results he arrives at may be accepted with implicit confidence. As he has asked me for species of *Cineraria*, I hope he may look into this matter also.

I must repeat my caution as to the danger of accepting horticultural evidence as to hybridity. I will give a few recent instances. I could easily give a long list with chapter and verse for each.

(*a*) *Thuya filiformis* was long considered to be a hybrid between *Juniperus virginiana* and a *Thuya*. It is now known to be a "growth-stage" of *Thuya orientalis*. The history is discussed by Sir Joseph Hooker in the *Gardeners' Chronicle* for June 22, 1861, pp. 575, 576. It affords a delightful commentary on the hybridisation fallacy and the value of "historical evidence."

(*b*) Some years ago we received at Kew bulbs of what professed to be a hybrid between *Amaryllis Belladonna* and *Brunsvigia Josephinae*. When it flowered, it was evident that it was no hybrid at all, but only a very fine form of the former species. This is rarely propagated from seed. In this particular case seminal variation had come into play with corresponding dimensional change. The hybrid origin is recorded in the *Gardeners' Chronicle* for September 4, 1875, p. 302. It will, no doubt, be dug out hereafter as "historical evidence."

(*c*) The last number of the *Gardeners' Chronicle* (June 1, 1895,

p. 692) affords a striking instance. Hybrid Cypripediums are of considerable pecuniary value. One recently exhibited at the Royal Horticultural Society was at once denounced as no hybrid at all, but a merely seminal variation. The possessor has fears that it will "add one more to the long list of doubtful crosses by which auctioneer and purchaser are alike misled."

Notwithstanding the Himalayan rabbit, I am afraid botanists will continue to refuse to accept hybrid origin on historical evidence unless there is palpable objective proof of the fact.

There are two additional bits of evidence, to which, however, I do not attach great weight, but which may be recorded to complete the story. It is, at any rate, agreed that the Cineraria originated from the Canaries. I have already pointed out that De Candolle divided the wild Canarian species into shrubby and herbaceous. I do not believe that they are mixed in the modern Cineraria, which remains entirely herbaceous. Now, Schultz-Bipontinus, who described the Canarian species for Webb and Berthelot, relegates the shrubby species to *Senecio*, and the herbaceous to *Doronicum*. Though this is not now sustained, it shows that the two groups are not very closely related, and diminishes the probability of their freely intercrossing.

On the other hand, *Cineraria cruenta* and the modern *Cineraria* cross with the greatest facility. In fact, if you grow the two together it is almost impossible to keep the wild species true. I have no doubt that in a short time we shall be able to combine the pleasing habit of the wild plant with the fine colour of the modern strains. All this does not surprise one, as to me they are all essentially the same thing.

I must add one word more. I cannot but think that there is a growing danger nowadays of a pseudo-biology growing up for the especial use of evolutionists. This is not the first time by many that I have been so unlucky as to come into collision with it. Long ago I pointed out in these pages that biology is not a deductive science, and for the present, at any rate, theory must be adjusted to facts, not facts to theory.

W. T. THISELTON-DYER.

Royal Gardens, Kew, June 1.

MR. BATESON now admits that *some* named varieties of *Cineraria* may have arisen from pure-bred *C. cruenta*, or from plants believed to be pure-bred. He holds that these have become extinct, while Mr. Dyer believes the hybrids to have disappeared. I have never attempted to discuss this question, and shall not do so now. I wish only to justify my interpretation of the passages I quoted against Mr. Bateson :—

(1) Mrs. Loudon begins the article quoted by both of us with these words : "Most of the purple *Cinerarias* are varieties, or hybrids, of *C. cruenta*." She then goes on to say that in or about 1827 (the year in which he recommended the growth of pure-bred *C. cruenta* "for the production of fine double and single varieties"), Drummond, of Cork, produced certain hybrids ; while since his time other hybrids had been made. She then, in a new paragraph, says : "Some of the most beautiful *Cinerarias* now in our greenhouses have been raised by Messrs. Henderson . . . particularly *C. Hendersonii* and the King, both raised from seeds of *C. cruenta*" ; and a line or two further : "Two new ones have lately been raised, of remarkably clear and brilliant colours, apparently from *C. cruenta*, named Queen Victoria and Prince Albert," &c.

It will be seen that the general statement, with which the article begins, declares "*most purple Cinerarias*" to be "*either varieties or hybrids*" of *C. cruenta*. Of others, and of those Cinerarias (such as "the King") which are not purple, nothing is said. This general statement is illustrated by examples, first of hybrids, next of pure-bred varieties.

In discussing the examples of pure-bred forms, Mr. Bateson omits to notice "Queen Victoria" and "Prince Albert," and discusses only *Hendersonii* and "the King." He believes Mrs. Loudon, in saying that these were "raised from seeds of *C. cruenta*," to mean simply that *C. cruenta* was the female parent, the male being unknown, or unnamed. I do not know what degree of inaccuracy Mr. Bateson is willing to attribute to Mrs. Loudon ; but in the writings of serious botanists a "seed" means the fertilised product of two elements, the ovule and the pollen grain ; and therefore the "seed" of *C. cruenta* means the product of two parents, both of which belonged to this species.

Mr. Bateson says that six or seven years after writing the passage in question, Mrs. Loudon speaks of *C. Hendersonii* and the King as "hybrids." This simply shows that she changed her mind ; and although it may affect the value of her opinion as evidence, it does not alter the plain meaning of her words in 1842.

(2) The only author whom I quoted as asserting the pure-bred origin of *C. Hendersonii* and the King was Mrs. Loudon. It is true that in two other articles quoted by Mr. Bateson these plants are called hybrids. I did not allude to this matter in my first letter, because I hoped Mr. Bateson would himself see the folly of attributing to these articles any definite meaning whatever. It will suffice to consider one of them.

In the earlier article, describing *C. Waterhousiana* (*Paxton's Mag. Bot.* iv. p. 219), that plant itself is called a "variety," although it is said to be the offspring of specifically distinct parents. On p. 221, *C. Hendersonii* is alluded to in these words: "The following are the names of some of the hybrids raised and cultivated by Messrs. Henderson . . . *C. cruenta var. Hendersonii*, *formosa*, &c." Both these passages are meaningless, if the words "hybrid" and "variety" are construed strictly. If they are not to be so construed, and they evidently cannot be, then I was justified in ignoring the passages, for they prove nothing but the incompetence of their author.

On the other hand, the passage which I did quote from this article is at least intelligible ; and it asserts that *C. cruenta* "may be regarded as *the parent*"—which means, if it means anything, the *only* parent "of many of those beautiful varieties so successfuly cultivated by Messrs. Henderson," &c. This passage Mr. Bateson does not consider in his reply to me.

The second article (*Paxton's Mag.*, 1842, p. 125) in which the King is called a hybrid, uses the word in the same loose fashion, and it would be as easy as unprofitable to quote other passages in which the same plants are called now "varieties" and now "hybrids."

Enough has been said to show that Mr. Bateson's original evidence does in fact bear the interpretation I put upon it ; and further, that the words "variety" and "hybrid" are so loosely employed by early writers that their records are often of little value. Stories of hybridism and sporting are frequently brought forward on such evidence ; so that I have thought it worth while to examine the case for one such story, as stated by its advocate. Having done this, my interest in the matter ends, and I do not propose to speak further upon it.

W. F. R. WELDON.

University College, London, May 31.

Some Bibliological Discoveries in Terrestrial Magnetism.

IN a letter on the above subject, by Dr. L. G. Bauer, published in NATURE of May 23 last, I read as follows : "I find it asserted that the Frenchman, L. J. Duperrey, was the first (1836) to construct 'magnetic meridians' for the whole earth, *i.e.* those lines on the earth's surface marking out the path described by following the direction pointed out by a compass needle." The writer then remarks that the honour of first introducing this method is due to Thomas Yeates, an Englishman, in 1817.

This is hardly correct, as I possess a coloured map of the Northern Hemisphere with the "magnetic meridians" as described shown upon it of an earlier date. The title of the map is :

"To George Washington,
"President of the United States of America,
"This Magnetic Atlas or Variation Chart is humbly inscribed by John Churchman."

As Washington died in December 1799, it is evident that John Churchman has a prior claim to being the first to construct "magnetic meridians." ETTRICK W. CREAK.

London, May 31.

Effects of Earthquake in Sumatra.

ON May 17, 1892, an unusually severe earthquake was felt through nearly the whole of North Sumatra ; most severely shaken was the district between the Dolok Lubuk Raja and the Ganung Talamau (Ophir). Serious landslips occurred in many parts of the mountains, especially near the summit and along the slopes of the Gunung Merapi, a volcano 2145 metres high in the residency Tapanuli. On inspection it was found that the safety of a brick pillar, erected on its most elevated point by the triangulation service, was endangered by part of the crater having been

destroyed. At three metres distant from the original pillar, as much as the narrow ridge would allow, a new pillar was built, the top of which was made level with that of the original one. The measurements made in order to fix the position of this new pillar showed such differences with the original measurements, that these could only be explained by a displacement of the original pillar. As, however, neither fissures nor local disturbances of the ground could be observed, new measurements were

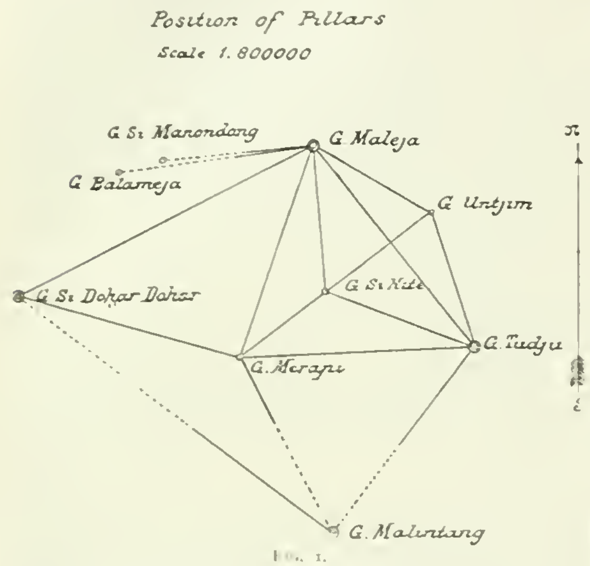

FIG. 1.

made from all the surrounding positions, and it was proved that a displacement of several more pillars had taken place.

Fig. 1 shows the position of the pillars before the earthquake: Fig. 2, their displacement by the earthquake. A detailed description of these measurements was published in the *Natuurkundig Tijdschrift*, vol. iv. part 3, by Captain Muller, the chief of the triangulation party. The longest distance over

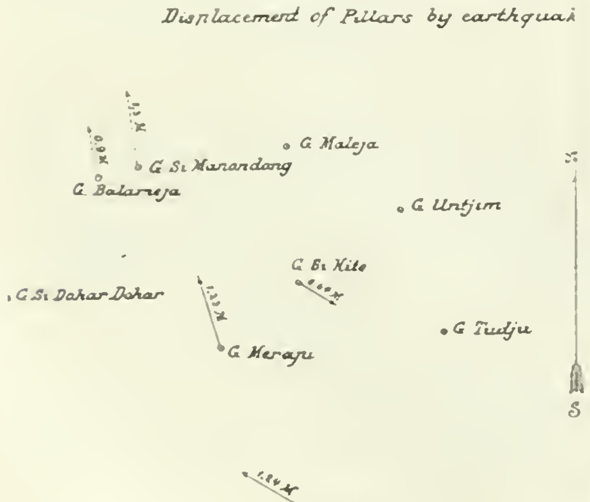

FIG. 2.

which a displacement was proved to have taken place was between the Gunong Malintang and the Dolok Balameja, or 53 kilometres. Captain Muller, however, has no doubt that if a new survey were carried on more southward, a displacement of more pillars—that is, a contortion of the surface over a larger area—would be found to have taken place.

Malang, April 14. TH. DELPRAT.

Instinct-Impulse.

THE note published in NATURE under date of April 18, in reference to my article in the April number of *Mind*, leads me to think that it may be well to explain my reasons for adopting the terminology there and elsewhere used by me, and which the writer of the note calls in question. I do so with the hope that this explanation may lead towards that "consensus of opinion on psychological nomenclature" that the writer of the note thinks is at present impossible.

The word "instinct," as my critic states, is generally applied "to the manifestation of particular activities." In other words, it is used by the biologist in an *objective* study of activities in animals, when he is not dealing with the nature of the conscious states coincident with these activities. It is thus, too, that I employ the word; but I have extended its use to cover certain manifestations of activities that do not take a large place in the considerations of the biologist, but that, nevertheless, appear to me to be of the same general nature as those "manifestations of particular activities" to which the word "instinct" is by current agreement applied.

What I claim is that the actions of one who is carried away by imitation, and the work of the philanthropist and of the artist, when objectively viewed, appear as "manifestations of particular activities," just as much as do the actions that go with self-defence and tribal protection, with care of the young, with nest-building, with migration, &c., and that therefore the term instinct, if applied to one set of such activities, may be applied to all.

If it be held that the objection to the extension of the use of the term lies in the fact that the activities that I speak of as due to the "imitation instinct," the "benevolent instincts" and the "art instincts" are not sufficiently *particular*, then I must answer that the fixedness of the actions involved is in all cases of instinct only relative; that this relative fixedness varies with the different instincts. In the self-preservative reactions, for example, we are able to predict the blow at the enemy, whilst the very varied actions by the animal mother in securing the safety of her young are unpredictable; but who hesitates to speak of the maternal "instincts"?

The word "instinct" then, in my view, should be used to indicate the manifestations of those animal activities which, when we consider them objectively, we see to have become emphasised because of racial values; of these values the acting animal (even if he be a man) may have no cognisance whatever. This is the usual use of the word, and there seems to me to be no scientific demand for any change in this usage.

On the other hand, I have suggested that we use the term "instinct feelings" to indicate the conscious coincidents of the animal activities that we call instinctive; and I have endeavoured to show that where these instinct actions are relatively fixed and forceful, then their coincident "instinct feelings" gain names, and form the class of psychic states known as the "emotions."

Furthermore, I object to the use of the word "impulse" in the description of these activities, as my critic suggests its employment, especially when they are objectively considered; for the word "impulse" is in general used to indicate those phases of consciousness which are produced by the *inhibition* of instinctive activities that have been stimulated by the presence of the objective condition that usually calls them out, but which for one reason or another are not at once realised. This, indeed, is the way in which the word is usually employed, not only by the psychologist, but in common speech as well. We speak of having an impulse to strike an enemy, not when we do strike him, but when the instinct to strike is held in check. What is more, I think this word "impulse" should be employed in this sense only; for the requirements of science do not demand its use with any other signification. I have discussed this matter of the nature of impulse rather fully at pp. 272, &c., in my book, "Pain, Pleasure, and Æsthetics," to which the writer of the above-mentioned note refers. HENRY RUTGERS MARSHALL.

New York, May 2.

THE term "instinctive" should, in my judgment, be applied to those activities which are congenital and which are also relatively definite; the term "instinct" being reserved for the subjective and affective condition of the performance of instinctive activities. Where the definiteness is the result of individual acquisition the term "instinctive" should not be applied, though it is so used by Prof. Wundt and others. The modern

controversy as to the inheritance of acquired characters seems to render insistence on the congenital element advisable. Undoubtedly there is an inherited tendency to imitation; but from the nature of the case, the activity performed through imitation is not congenitally definite.

With Mr. Marshall's statements concerning impulse I cannot agree. If we say in common speech that "the instinct to strike is held in check," we also say that the impulse to strike is held in check. The control of our lower impulses is an important part of our moral life; but the contention that the impulses are "produced by the inhibition," is open to serious criticism.

THE WRITER OF THE NOTE.

RECENT EXCAVATIONS AT THE PYRAMIDS OF DAHSHÛR.

FEW sources have supplied more facts for the study of anthropology than the Egyptian tombs, and the most important necropolis of Egypt is situated south-east of Cairo, close to the remains of ancient Memphis.

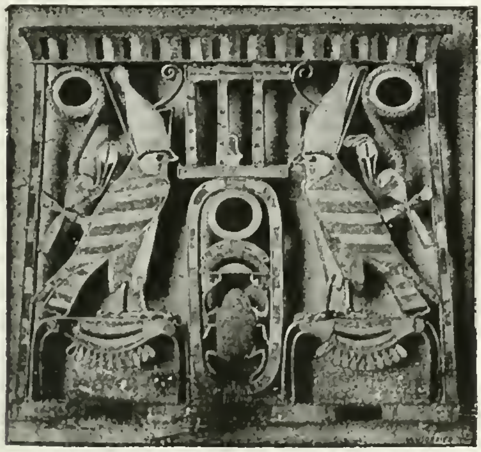

FIG. 1. Pectoral belonging to Usertsen II. (Found March 7, 1894.)

This stretches from the village of Abou-Roash on the north to that of Médûm on the south, about a distance of twenty-five miles.

To the south, and at the end of the great chain of pyramids, are those of Dahshûr, of which four are of stone and two of brick. Up till 1892 the history of two of these still remained to be unravelled, but in that year a large party of excavators, headed by M. de Morgan, set out, and succeeded in opening up both these pyramids. It is to this interesting work we wish to draw attention, for it marks an important step in Egyptology, indicating some of the earliest applications of science in one direction known to us, while ancient art is at the same time illustrated. M. de Morgan has recently given an account of his explorations in *Le Monde Moderne*, and we are indebted to the courtesy of the Editor of that magazine for the illustrations of the finds.

The two pyramids are of brick, and covered with a layer of limestone; each one was surrounded by a brick wall, which showed the limits of land reserved for the use of the royal family. Round this was an avenue, left out of respect to the descendants of the gods; then came the tombs of the great people connected with the court. From inscriptions found, there is every reason to believe that these two pyramids belonged to Usertsen III. and Amen-em-hât III., both of the Twelfth Dynasty. On the north side of the more northerly one are the tombs of some princesses, four among them more important than the rest.

These tombs have been plundered, for, owing to the Egyptian custom of burying jewels with their dead, the pyramids have ever been a favourite resort of robbers; and thus it is that some of the tombs are in great disorder, which causes much hindrance to the scientific research now being carried on, more especially as many documents have been carried away. Still, the plunderers have not stripped them entirely, and the remaining documents and treasures have been a most important clue to finding out the dates of the pyramids and the history of the people they entomb.

This spoliation of the tombs, continued by each successive generation, was not stopped till the celebrated Mariette founded the "Service for the Conservation of Monuments in Egypt."

Amongst the most interesting and perfect pieces of jewellery found are three pectorals. They were found in the princesses' tomb, and had been hidden in the soil in order, no doubt, to deceive the plunderers.

Fig. 1, the first one unearthed, has in the centre the cartouch of Usertsen II., held by two hawks, which bear the crown of Lower and Upper Egypt. The signs of the cartouch are made of cornelian, lapis-lazuli, and turquoise, set in gold; the other figures are likewise set with precious stones. The other two pectorals are similarly executed. The first (Fig. 2) represents two men, each in the act of striking with a club an Asiatic captive who they are holding by the hair. In the centre is the double cartouch of the king, and on each side the emblem of life, out of which protrude two arms holding a flabellum. Above them all is an eagle with outspread

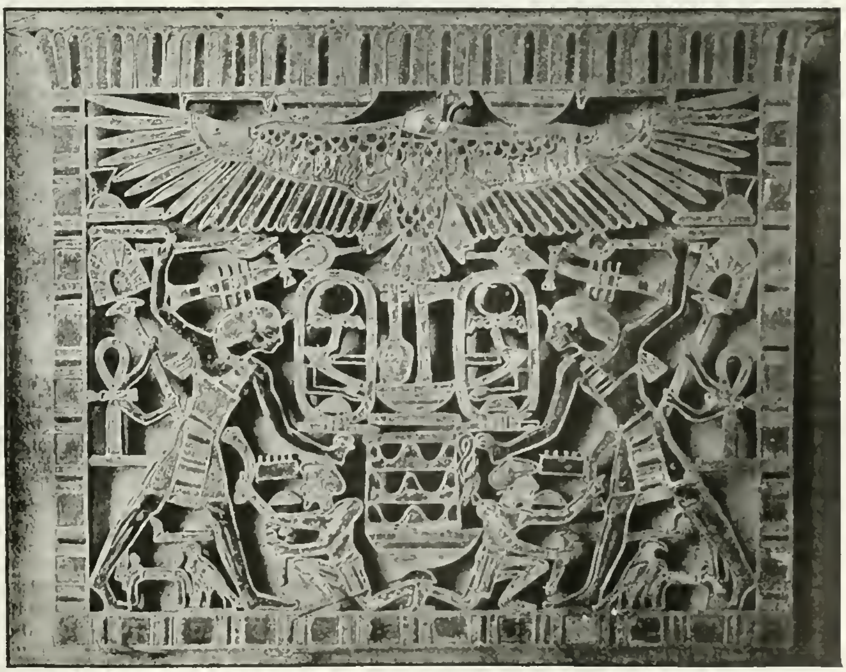

FIG. 2. Pectoral belonging to Amen-em-hât III. (Found March 8, 1894.)

wings, having in its claws the symbols of eternal life and stability. The second one (Fig. 3) has similarly an eagle with outspread wings, and beneath it is the cartouch of Usertsen III. To the right and left is a sphinx with the head of a hawk, on which are the feathers of Ammon; each is standing on a captive, whilst in front of each kneels an interceding Asiatic prisoner.

The workmanship of these jewels is wonderful. The perfection with which the precious stones are set, and, moreover, the delicacy and freshness of the whole, makes it hard to believe them five thousand years old. The work shows how far science dates back, and is evidence that in the case of the Egyptians, the further we look back, the higher we find their culture.

It is a curious fact that when we compare these jewels with those of a later period, we should find them far superior in workmanship; but so it is, for those of the time of the Ramessids are but an imperfect edition of the more ancient ones, not nearly so artistic, nor yet so well finished off.

When the excavations were continued, five large barges were brought to light; it was not till the work had continued some time that the royal apartments were found, so cleverly were they hidden.

The pyramid of the south is the most southerly royal monument of the Memphite necropolis. Traces are still to be found of a wall round it, and similarly situated as

Fig. 3.—Pectoral belonging to Usertsen III.

the princesses' tombs at the pyramid of the north; here, too, we find a gallery of twelve vaults or tombs, of which only two contain mummies, one being King Ra-Fou-Ab, and the other a princess, Queen Noub-Hotep.

Near the king's sarcophagus is a small chamber, in which were a quantity of broken vases and chests, and in a great wooden tabernacle was a statue of the *double* of the deceased (Fig. 4), painted grey, representing a young man of fifteen or sixteen. It is made of hard wood, almost black, and is admirably done; every muscle and bone are perfectly placed, and specialists have certified it [illegible]. It is a fine piece of Egyptian sculpture, of which only four good specimens have descended to [illegible]. Some savants have endeavoured to classify what has been found into certain schools, but this is scarcely advantageous till more has been collected.

The well leading to the princesses' tomb is about 13 ft. deep. At the bottom is a vaulted brick passage, which formerly ended in a wall. As was suspected, the wall being removed revealed a vault containing a flagstone, on which were water jars, pieces of embalmed meat, and other offerings, also two cases containing many things pertaining to the toilet. No inscriptions were found until the flagstone was removed, and a coffin brought to light on which were many texts relating to the name and title of the princess. As this tomb is so similar to that of King Ra-Fou-Ab, and is so closely situated, it is supposed that the princess was his wife; but nothing has been found to confirm her marriage with him.

Fig. 4.—Statue of double of the King Ra-Fou-Ab. (Found April 16, 1894.)

Although a great deal has been done, it will require many years of hard work to open up all the tombs in the Dahshûr necropolis; but general interest has now been awakened, thanks to those who have been the means of making us acquainted with the preceding facts; the results of future action will be followed by many.

NOTES.

Prof. Cornu, the Vice-President of the Paris Academy of Sciences, is now in England, and will deliver the discourse at the Royal Institution to-morrow evening. On Tuesday evening he was entertained by the members of the Athenæum Club who are members of the Institut de France, either as Associates or Correspondants. There were present, representing the Académie des Sciences, Lord Kelvin (Associate), Sir H. Gilbert, Mr. Huggins, Mr. Lockyer, Admiral Sir G. H. Richards, and Mr. Sylvester (Correspondants); representing the Académie des Inscriptions, Sir J. Evans and Sir E. Maunde Thompson; representing the Académie des Beaux Arts, Mr. Herkomer. Letters of regret for unavoidable absence were read from Mr. Frankland and Sir Joseph Lister, Associates of the Académie des Sciences; and Sir J. Hooker, Lord Rayleigh, Sir A. Geikie, Dr. Williamson, and Sir H. Roscoe, Correspondants; Académie des Beaux Arts, Sir J. Millais, Mr. Alma-Tadema, Sir E. Burne-Jones; Académie des Sciences Morales et Politiques, Mr. Goschen, Mr. Bryce, Mr. Lecky, and Sir F. Pollock.

Mr. Herbert Spencer has been created by the German Emperor a foreign Knight of the Order Pour le Mérite. Another mark of the esteem in which he is held is his election as an Honorary Member of the Vienna Academy of Sciences.

Sir Archibald Geikie has just been elected a Corresponding Member of the same Academy.

Dr. Backlund has been appointed Director of the Pulkova Observatory, and Dr. Hermann Struve will succeed the late Dr. C. F. W. Peters as Director of the Königsberg Observatory.

It is noted in *Science* that Deputy Surgeon-General J. S. Billings will shortly leave the Army Medical Museum, of which he is curator, and the Library of the Surgeon-General's Office, of which he is librarian, having accepted the chair of Hygiene in the University of Pennsylvania. Dr. Billings hopes to complete his work on the final volume of the great Index Catalogue before his retirement.

Dr. John Anthony, whose name is familiar to many workers in microscopy, died at Birmingham on Monday, at eighty-one years of age.

The death is announced of Prof. Franz Ernst Neumann, Honorary President of the Physikalisch-Okonomische Gesellschaft at Königsberg. Prof. Neumann died on May 23 at the advanced age of ninety-seven, having been born September 11, 1798. He was eminent in the department of mathematical physics, and was elected a foreign member of the Royal Society of London in 1862.

Among other deaths of scientific men abroad, we notice that of Dr. John Byron, well-known for his bacteriological researches. He was bacteriologist in the Loomis Laboratory, and lecturer on bacteriology in the University Medical School of New York. Dr. Byron is believed to have contracted the disease of which he died, by inhaling tubercle bacilli while carrying out some experiments. The deaths are also announced of Dr. O. Ke[illegible]h., at Berlin; Dr. F. Müller, the zoologist, at Basel; and Brigadier-General Charles Sutherland, formerly Surgeon-General of the United States Army, at Washington.

The Harveian Oration will be delivered at Edinburgh on June 28, by Dr. Yellowlees.

The Secretary of State for the Home Department has requested the following gentlemen to inquire into and report on the manufacture, filling, and use of gas cylinders:—Prof. C. V. Boys, Prof. H. B. Dixon, Dr. A. Dupré, the Rev. F. J. Smith, and Prof. W. C. Unwin. Mr. Robert F. Reynard, of the Home Office, will act as secretary.

Acting under the Wild Birds Protection Act, 1894, notice has been given by the Home Secretary, that the taking or destroying of the eggs of the "barn owl, brown or wood owl, long-eared owl, short-eared owl, common buzzard, merlin, kestrel, goldfinch, black-headed gull, peregrine falcon, kingfisher, dotterel, raven, heron, bittern, woodcock, dipper or water ouzel, and golden plover," is prohibited in any part of the county of Westmorland.

The preliminary programme for the sixty-third annual meeting of the British Medical Association, to be held in London from July 30 to August 2, is given in the *British Medical Journal*. The President, Sir J. Russell Reynolds, will deliver his address on July 30. The Address in Medicine will be delivered by Sir William Broadbent on the following day. Mr. Jonathan Hutchinson, F.R.S., will give the Address in Surgery on Thursday, August 1, and the Address in Physiology will be given by Prof. E. A. Schafer at the concluding meeting on August 2.

At the annual general meeting of the Institution of Civil Engineers, held last week, Sir B. Baker was elected President, and Mr. J. Wolfe Barry, C.B., Mr. W. H. Preece, C.B., Sir Douglas Fox, and Mr. James Mansergh Vice-Presidents. The members of the Council are Dr. W. Anderson, Mr. Alex. R. Binnie, Mr. W. R. Galbraith, Mr. J. H. Greathead, Mr. J. C. Hawkshaw, Mr. C. Hawksley, Dr. John Hopkinson, Dr. Alex. B. W. Kennedy, Sir G. L. Molesworth, Sir Andrew Noble, Sir E. J. Reed, Mr. W. Shelford, Mr. F. W. Webb, Sir W. H. White, and Sir E. Leader Williams.

We have received from Dr. P. Bergholz, Director of the Meteorological Observatory at Bremen, the results of the hourly observations made during the year 1894, with rainfall values obtained from four stations in the suburbs. This observatory forms part of the regular German meteorological service, and the results are therefore given in the form recommended by recent congresses; but in addition to the prescribed observations the work contains other valuable information, *e.g.* phenological observations, and the dates of freezing and clearing of the Weser since 1818. This table shows that the most prolonged frosts during that period were in 1844-5, 1846-7, 1857-8, and 1870-1. In each case the Weser was frozen over for two months or upwards. We observe, however, that the publication of the data is to be discontinued, as that river is now kept free for navigation by artificial means. A graphical representation of the principal meteorological results gives a ready means of comparing the characteristics of the different months.

The Egyptian Government have published an important paper on the climate of Cairo and Alexandria, based on observations taken between 1886 and 1890, and discussed by Dr. Engel, chief of the Statistical Service. The work contains a number of tables and diagrams, together with introductory text, from which we extract a few of the results obtained. At Cairo, the mean annual temperature for the five years was 70°·3, the absolute maximum being 118°·2 on June 13, 1886, and the lowest 33°·8 on January 1, 1890. The average yearly number of rainy days was twenty-four, and the amount 1·2 inch only. At Alexandria the mean temperature was 68°·5, the absolute maximum being 100°·6, on May 10, 1889, and the minimum 43°·9, on January 22, 1880. The average number of rainy days was forty, and the amount 8·2 inches. The principal difference in the climate of the two places consists in the diurnal and seasonal variations of temperature. Cairo is much the hotter of the two places in summer, but cooler than Alexandria in the winter; and the differences in the extreme temperatures are much greater at

Cairo, both as regards days and seasons. Relative humidity varies much more at Cairo than at Alexandria, but it is much lower at Cairo in summer, and a little higher in winter than at Alexandria; while, on the contrary, the absolute humidity varies much more at Alexandria, being very high in summer and considerably greater than at Cairo. Both places enjoy a large amount of sunshine, but fog occurs occasionally, more particularly at Cairo in the early morning.

A MOST important contribution to the study of the formation of dolomite is made by M. C. Klement, in the *Bull. Soc. Belge Géol. Paléontol. et Hydrol.* After describing the history of theories of dolomite, the author calls attention to the frequent occurrence of dolomite in the form of coral-reefs, as observed by Dupont in the Devonian, by Richthofen and Mojsisovics in the Trias, and by Dana in the recent raised reefs of Metia in the Pacific. He points out that while in the chemical experiments that have been made with a view of dolomitising carbonate of lime, *calcite* has always been operated on, the substance of coral has been shown by Sorby to be probably *aragonite*. The author has therefore carried out a large series of experiments on the action of the constituents of sea-water (particularly magnesium sulphate) on aragonite, the results of which are given at full length. From these he finds (1) that a solution of magnesium sulphate, in the presence of sodium chloride, and at a temperature of 60 C. or more, decomposes aragonite with formation of a magnesium carbonate the exact composition of which is difficult to determine, owing to the impossibility of isolating it from the residual aragonite; (2) that this action increases with the *rise of temperature*, and with the *concentration* of the solution, and is greatly diminished by the absence of sodium chloride; (3) that recent coral is attacked by magnesium sulphate just as mineral aragonite is; and (4) that the lagoons of modern coral-reefs afford all the conditions of temperature, saturation, &c., necessary for the production of magnesium carbonate in the manner of his experiments. While recognising, therefore, that dolomites may have been formed in more ways than one, M. Klement concludes that one of the most usual ways of formation of dolomite in nature has been the action of heated and concentrated sea-water in coral-lagoons on the aragonite of coral and other skeletons, with formation of carbonate of magnesium, which is subsequently, perhaps after solidification of the rock, with the remaining carbonate of calcium, converted into massive dolomite.

THE last number of *Modern Medicine and Bacteriological Review* is of exceptional interest, inasmuch as it contains an original article by Prof. Metchnikoff, of the Pasteur Institute, on "the extra-cellular destruction of bacteria in the organism." This article is really a critical comment upon some of the conclusions deduced by Dr. Pfeiffer from his experiments on the destruction of cholera vibrios in the peritoneal cavity of guinea-pigs. Dr. Pfeiffer observed this destruction of cholera vibrios when the latter were introduced into animals previously vaccinated against this germ, and also in the case of unprotected animals when the vibrios were injected together with a small quantity of serum from vaccinated animals. In both cases Dr. Pfeiffer found that they were destroyed *outside* the cells in the peritoneal fluid, and he believes that this bacteria-killing fluid is secreted by the cellular elements in consequence of a special excitation produced by the injection of cholera vibrios, and that the immunity acquired by guinea-pigs is independent of phagocytosis. Prof. Metchnikoff, however, regards this as an episode in the battle between bacteria and phagocytes, and maintains, on evidence supported by experiments, that the leucocytes secrete this bacteria-killing fluid whilst undergoing a process of degeneration due to the injection of Pfeiffer's mixture of vibrios, serum, and broth. That although unable to engulf the vibrios, they are able still to destroy them by their secretions. Metchnikoff points out that if before introducing the vibrio-mixture, a few cubic centimetres of broth be injected into the peritoneal cavity, the leucocytes will gather together in great force after a few hours, and if the vibrio-mixture be then introduced, phagocytosis does take place, and the cholera bacteria are more rapidly destroyed by this process of intra-phagocytosis than by the extra-cellular destruction produced by the conditions of Pfeiffer's experiments. The mechanism of immunity is surrounded with so many complicated problems that the search for its solution, whilst one of the most interesting tasks afforded by the developments of bacteriology, must still remain one of the most puzzling and difficult.

THE current number of the *Journal de Physique* contains an important paper by M. P. Curie on the magnetic properties of bodies at different temperatures. The author has examined the magnetic properties of a number of substances in fields of from 25 to 1350 C.G.S. units, and in some cases for temperatures from 15° to 1370° C. The body under observation was generally in the form of a coarse powder, and was enclosed in a glass bulb, which was placed in a non-uniform magnetic field produced by two electro-magnets. The force acting on the body was measured by means of the torsion of a wire. For the purposes of heating the glass bulb was surrounded by a fine clay jacket, and this latter was heated by a wire in which an electric current was passed, the temperature being measured by means of a thermo-electric junction. In the case of diamagnetic bodies, with the exception of bismuth and antimony, the author finds that temperature has practically no effect on their magnetic properties. Fusion and allotropic modification also seem to produce no effect, so that the magnetic properties of a body seem to depend not on the arrangement, but rather on the nature of the molecules of the body. Selenium, however, is an exception, for in this case the susceptibility is about 3 or 4 per cent. smaller in absolute value in the liquid than in the solid state. Phosphorus is another exception, for the susceptibility of the different allotropic modifications are slightly different. The susceptibility of bismuth increases with rise of temperature, according to a straight line law, up to the melting-point, where there is a sudden rise. The susceptibility of melted bismuth is independent of temperature, and is very nearly 0. Observations made on oxygen show that the coefficient (K), which, when multiplied into the strength of the magnetic field, gives the magnetic moment of the body per unit mass (the author calls this the coefficient of specific magnetisation), is independent of the pressure, and is between 20° and 450 inversely proportional to the absolute temperature. In the case of solutions of paramagnetic salts, K is also found to vary inversely as the absolute temperature; thus supporting the observations of Wiedemann and Plessner on this subject. Glass when cold is generally feebly diamagnetic; when heated, however, it becomes much more strongly diamagnetic. The rate of increase of the diamagnetism decreases as the temperature rises; above 300° C. no further change takes place. The author considers these changes to be due to the fact that glass consists chiefly of a diamagnetic substance, the properties of which remain unaltered when the temperature rises, and of a small quantity of a relatively strongly paramagnetic substance, the para-magnetism of which decreases as the temperature rises.

MESSRS. GEORGE PHILIP AND SON will shortly publish "The Exploration of Australia," by Mr. Albert F. Calvert. This book is designed to form a companion volume to Mr. Calvert's work, "The Discovery of Australia," and will trace the progress of maritime and land exploration from the period of Captain Cook, up to recent times.

A TRANSLATION, by Mr. W. E. Baxter, is announced of Van Heurck's important treatise on the Diatomaceæ. It will contain

about 2000 figures, illustrating every known genus of diatoms, and every species found in the North Sea and countries bordering it, including Great Britain.

THE second edition of "Elements of Marine Surveying," by the Rev. J. L. Robinson, lately published by Messrs. Macmillan and Co., contains several very useful additions and improvements. Young marine surveyors will find the volume an excellent aid to the study of the theoretical side of their profession, and would do well to include it in their outfit.

PARTICULARS of editions of Gilbert White's "Natural History and Antiquities of Selborne" have been compiled by Mr. Edward A. Martin, for the Selborne Society. Since the original edition was published in 1789, twenty-three other editions have appeared. The list compiled by Mr. Martin, gives the dates of the various editions, publishers, printers, editors, number of pages, and general description.

THE annual report of the Royal Botanic Gardens, Trinidad, for the year 1894, compiled by the Superintendent, Mr. J. H. Hart, furnishes evidence of the practical value of these colonial botanic gardens, and of their relation with the central institution at Kew. Under the Economic Section, information is given of the growth in the island of the sugar-cane, cacao, coffee, yam, gambier, vanilla, the Brazil nut, and cola, and of the principal enemies of these crops, and the best mode of combating them.

WE have received Part i. of "The Flowering Plants and Ferns of New South Wales," with especial reference to their economic value, by Mr. J. H. Maiden, assisted by Mr. W. S. Campbell, and issued under the authority of the Department of Mines and Agriculture for New South Wales. The present part contains descriptions and coloured drawings of four species—*Telopea speciosissima*, *Eucalyptus corymbosa*, *Actinatus helianthi*, and *Acacia glaucescens*. It is intended in this way to illustrate the principal flowering plants and ferns of the colony.

THE additions to the Zoological Society's Gardens during the past week include a Panolia Deer (*Cervus eldi*, ♂) from Hainan, presented by Mr. Julius Neumann; a Ruddy Ichneumon; (*Herpestes smithii*) from India, presented by the Earl of Hopetoun: a Spotted Ichneumon (*Herpestes nepalensis*) from India, presented by Mrs. Thompson; a Rosy-faced Love-Bird (*Agapornis pullaria* from West Africa, presented by Mr. Cecil M. Bevan; a Rufescent Snake (*Leptodira rufescens*) from South Africa, presented by Mr. J. E. Matcham; a Spiny Tree Porcupine (*Sphingurus spinosus*) from Peru, a Blossom-headed Parrakeet (*Palæornis cyanocephala*) from India, two Tuberculated Iguanas (*Iguana tuberculata*) from South America, deposited; two Guira Cuckoos (*Guira pirirgua*) from Para, purchased; a Japanese Deer (*Cervus sika*, ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE MOTION OF THE SOLAR SYSTEM.—The methods elaborated by Argelander and Airy for the numerical solution of this problem have been followed with more or less variation by a host of investigators. As a rule the deviations in method have involved matters of detail rather than any fresh departure. Various suppositions have been made as to the motions of the stars themselves (*motus peculiares*): that the magnitude and direction of these motions have no connection with position, or that, in general, all these motions take place with the same angular velocity parallel to the galactic circle. Stars may be grouped according to their brilliancy, or the amount of their proper motion, or they may be arranged with more or less ingenuity according to their apparent position; but when the final equations are solved, the results are found to be fairly accordant. This fact has been recently demonstrated by M. Pannekoek, who, to vary the problem as much as possible, has based his investigations on the type of spectrum presented by the star. The zone from which the stars are selected is somewhat limited, being restricted to 0°—20° of declination, the spectra of which have been observed at Potsdam. The stars have been divided into four groups, according to the amount of the proper motion, with the following results:—

Stars of the First Type.

	No. of stars.	Centennial proper motion.	Position of apex. R.A. (α).	Declination (δ).
		"	°	°
I.	203	2·11	322·8 ± 19·2	+ 14·7 ± 7·0
II.	93	5·58	304·7 ± 4·6	+ 12·1 ± 3·4
III.	58	9·84	275·8 ± 6·1	+ 18·3 ± 3·6
IV.	48	34·36	251·6 ± 12·1	+ 33·0 ± 7·3

Stars of the Second Type.

I.	77	2·07	274·6 ± 9·6	− 2·6 ± 6·3
II.	52	5·93	280·1 ± 9·9	+ 35·8 ± 6·5
III.	65	20·85	268·6 ± 7·1	+ 31·4 ± 4·6

The result derived from stars of small proper motion of either the first or second type of spectra is scarcely accordant with previous investigations. The Right Ascension of the one and the Declination of the other are sensibly different from results involving larger numbers of stars. The author remarks, however, that all the values in R.A. can be rendered less discordant by an increase in the constant of precession of +0″·01, and in Declination by assuming a constant negative error in the proper motions themselves. Here we have again evidence that no rearrangement of groups materially alters the position assigned for the apex of the sun's way; but when processes sensibly different in their conception are employed, the accordance in the results is not so gratifying. For instance, the attempt to determine the position of the apex from Vogel's measurements of the motion of stars in the line of sight led to either of the two results, according to the method of "weighting" employed.

	I.	II.
α	206°·1 ± 12°·0	159°·7 ± 20·2
δ	+ 45·9 ± 9·2	+ 50·0 ± 14·3

Here, if the Declination be fairly satisfactory, the Right Ascension is hopelessly discordant. On the other hand, Dr. Kobold's treatment of the problem according to the graphical method suggested by Bessel, a method which does not easily lend itself to numerical treatment, gives a fairly satisfactory result in R.A., but the Declination will scarcely be accepted. The position assigned to the apex by this method is $\alpha = 266°·5$; $\delta - 3°·1$. This result is based on 1425 stars, and ought to be entitled to considerable weight if it could be satisfactorily demonstrated that all ambiguity, which arises from the definition of the poles of the great circles in which the proper motions take place, had been satisfactorily removed. This question is still *sub judice*, and while distinct methods give conflicting results, it is not wise to insist too strictly on the direction of the motion of the solar system.

THE ROTATION OF MARS. Among numerous observations of the planet Mars during the last opposition, Mr. Percival Lowell gave his attention to the measurement of the longitudes of some of the more conspicuous markings. The observations covered 36 points in all, and were made with a power of 440 on the 18-inch refractor of the Lowell Observatory. The first fact that emerged from the observations was that all the longitudes as given in Marth's ephemeris were affected by a systematic error of about 5°; or, in other words, the Martian features were retarded by about twenty minutes as compared with the computed times. The cause suggested for the discrepancy between the calculated and observed positions is that the received time of rotation of the planet is a trifle too small, and that the longitudes are consequently falling slowly behind their predicted times of meridian passage.

A somewhat similar discrepancy appears to have been noted by Prof. Keeler in 1892, who ascribed it partially to the constant error in estimating the position of the diameter of a large disc (*Astrophysical Journal*, May).

THE SUN'S STELLAR MAGNITUDE.—A new method of computing this important constant, being the number representing the sun's brightness on the scale in which the magnitudes of stars are represented, has been employed by Mr. Gore (*Knowledge*, June). Taking one of the outer planets, the known size and distance

enable us to determine the fraction of the sun's light which it receives, and correcting for the albedo, it is easy to calculate the brightness of the sun in terms of that of the planet, the exact stellar magnitude of which can be found by direct measurement. Thus, Mr. Gore finds that the apparent diameter of Mars in opposition, as seen from the sun, is 0″·17, so that the area of the disc is 20·9 square seconds. Dividing the number of square seconds in a hemisphere by the latter, it is found that if the surface of Mars were a perfect reflector, the sun as seen from Mars would be 8,940,450,000 times brighter than Mars appears to us when in opposition.

According to Zollner, the reflecting power of Mars is only 0·2672, so that the previous number must be raised to 33,459,768,000. This, however, is for mean distance 1·5237, so that when reduced to the earth's distance (by multiplying by the square of 0·5237), we get the light of the sun as seen from the earth to be 9,174,008,385 times the light of Mars when in opposition; this number, on the basis of a light ratio of 2·512 corresponding to a difference of 1 magnitude, represents 24·9 magnitudes. Prof. Pickering's photometric measurements show that the stellar magnitude of Mars at mean opposition is 2·25, so that the deduced stellar magnitude of the sun is −27·15. Similar calculations from the data relating to Jupiter give a value of −27·17, and from Saturn −27·11. Though agreeing so remarkably among themselves, these new values differ very considerably from the value hitherto adopted, namely −25·5. The new value, however, receives confirmation in the fact that it is very nearly equal to the magnitude which α Centauri would assume if it were brought to the sun's distance from the earth, assuming the parallax to be 0″·76, the spectrum of this star resembling the spectrum of the sun.

THE GREENWICH OBSERVATORY.

THE Report of the Astronomer Royal to the Board of Visitors of the Royal Observatory, Greenwich, was read at the annual visitation on Saturday. A few of the developments made during the year covered by the report, and some observations of interest, are referred to in the subjoined extracts.

Provision has been made in the Navy Estimates for the erection in Greenwich Park of a magnetic pavilion for absolute determinations of the magnetic elements, and the plans are now being prepared in the Director of Works' Department. It is proposed to establish this station in the immediate neighbourhood of the Observatory, and at such a distance that there would be no suspicion of disturbance from the iron in the buildings.

WORK WITH EQUATORIALS.

The flint and crown discs for the new photographic telescope of 26 inches aperture, the gift of Sir Henry Thompson, have been received at the Observatory. The details of the design for the mounting have been carefully worked out, and good progress has been made with the mechanical work.

The 28 inch refractor has been in use throughout the year, and is quite satisfactory. It moves easily in R.A. and Declination, the new slow motion screws work successfully, the water clock in general drives it with great precision, and the performance of the object glass under good atmospheric conditions is admirable. Various improvements in the accessories of the instrument have been carried out in the past year. A spectroscope specially adapted to photography, for use with this refractor, is being made.

Micrometer measures of sixty three double stars have been made; in 27 of these the distance of the components was under 1″ and in 13 it was 0″·5 or under. The most remarkable of these measures are those of κ Pegasi (β 989). The components of this star, though only 0″·14 apart, were distinctly separated with a power of 1030.

Measures of the positions of satellites of Mars near elongation were made on two nights. Several attempts were also made to measure Jupiter's fifth satellite, but the results obtained were [illegible]. A series of measures of the polar and equatorial diameters of Jupiter and his satellites was made. Measures of the diameters of Saturn and his rings and the positions of the satellites have also been made, and are being continued.

With the astrographic equatorial 595 plates, with a total of 1450 exposures, have been taken. Of these, 162 have been rejected for various reasons, such as: partially fogged plates; because the réseau lines were not clearly printed; because the images were too faint to show 9th magnitude stars with a twenty-seconds exposure; for faults in development; for mistakes of setting; and for miscellaneous defects. It is hoped that a much smaller number of plates will need to be rejected in future for these causes.

The total number of celestial fields photographed since the commencement of work for the chart is 422, and the total number of fields photographed for the catalogue is 617. Only half as many fields for the chart and catalogue have been photographed this year as during last year. This is due partly to the unfavourable weather, and partly to the telescope being out of use for two months while the shutter of the dome was being repaired.

SPECTROSCOPIC AND HELIOGRAPHIC OBSERVATIONS.

Since 1894 December 19, when the spectroscope was brought into adjustment, 98 measures have been made of the displacement of the F line in the spectra of 13 stars, and 16 of the *b* line in the spectra of four stars. Some experiments have also been made in photographing stellar spectra, to give data as to the work to be done with the new photographic spectroscope.

Photographs of the sun were taken with the Dallmeyer photoheliograph on 199 days, and of these 375 have been selected for preservation, besides 18 photographs with double images of the sun for determination of zero of position-angle.

The 9-inch photographic telescope presented by Sir Henry Thompson, which has been mounted on the Lassell equatorial, was also in regular use as a photoheliograph up to October 15, when the progress of the building operations prevented its further use. Photographs of the sun had been obtained with it by that time on 80 days, of which 121 have been selected for preservation. In all, with one photoheliograph or the other, a record of the state of the solar surface has been secured on 213 days during the year.

The mean daily spotted area of the sun was only slightly smaller in 1894 than in 1893, the marked falling off in the spring of 1894 noted in the last report being followed by an increase during the summer months. The number of sun-spots was greater than in 1893. The spring of this year has shown a decline both in the number and area of spots.

MAGNETIC OBSERVATIONS.

The variations of magnetic declination, horizontal force and vertical force, and of earth currents have been registered photographically, and accompanying eye observations of absolute declination, horizontal force, and dip, have been made as in former years. Increased magnetic activity was shown in the year 1894, and great disturbances occurred on July 20 and August 20; the spot of light of the vertical force magnet, on the former date, and the spots of light of the horizontal force and vertical force magnets, on the latter, having passed beyond the range of the registering sheets for some hours. In July and August the disturbances in the earth-current registers caused by the South London Electric Railway showed a great increase, which is presumably due to the experiments then being made in the use of motors on the carriages of the railway instead of separate locomotives.

The following are the principal results for the magnetic elements for 1894:

Mean declination	17° 4′·6 West.
Mean horizontal force	3·9661 (in British units).
	1·8287 (in metric units).
Mean dip	67° 16′ 5″ (by 9-inch needles).
	67 17 8 (by 6-inch needles).
	67 18 43 (by 3-inch needles).

In the year 1894 there were ten days of great magnetic disturbance and thirteen other days of lesser disturbance. Tracings of the photographic curves for all of these days are being made, and will be published in the annual volume according to the arrangements made with M. Mascart. The calculation of diurnal inequalities from five typical quiet days in each month has been continued.

METEOROLOGICAL OBSERVATIONS.

The registration of atmospheric pressure, temperature of the air and of evaporation, pressure and velocity of the wind, rainfall, sunshine, and atmospheric electricity has been continuously maintained, except that during the winter the register of atmospheric electricity was interrupted during the greater part of February by freezing of the water in the exit pipe.

The mean temperature of the year 1894 was 49°·9, being 0°·5 above the average for the fifty years 1841-1890. The severe frost which set in on December 30, and continued with slight intermission until March 9, was the most remarkable meteorological feature of the year. The cold wave, defined as the period during which the mean daily temperature was below the average, extended from 1894 December 30 to 1895 March 9, with a break from January 14 to 20, and on March 1, a period extending over seventy days in all. The total defect of mean daily temperature below the fifty years' average during this period was 489°, or 7°·0 per day.

A comparison with some of the coldest winters since 1841 is given in the following table:—

Period of cold wave.	Number of days.	Total defect of mean daily temperature.
1845 Jan. 27—March 21	54	443°
1855 Jan. 10—Feb. 24	46	467°
1870 Dec. 21—1871 Feb. 3	45	320°
1886 Jan. 5—March 18	73	408°
1890 Nov. 25—1891 Jan. 22	59	560°
1894 Dec. 30—1895 March 9	70	489°

The cold on the four days February 6, 7, 8 and 9 was particularly severe, the mean temperature being 18°·6 or 20°·5 below the average of the 50 years from 1841-1890, and there is no other instance of four consecutive days since 1841 with so low a temperature.

The lowest temperature recorded during the winter was 6°·9 on February 8, the lowest temperature in February since 1841, the next lowest being 7°·7 on 1845 February 12. Lower temperatures have been registered twice since 1841, viz. 4° on 1841 January 9 and 6°·6 on 1867 January 5. The mean temperature throughout the whole of February was 28°·9, or 10°·5 below the 50 years' average. The mean in February 1855 was 29°·2.

The mean daily horizontal movement of the air in the twelve months ending 1895 April 30 was 283 miles, which is slightly above the average. The greatest movement was 867 miles on December 22, and the least 50 miles on August 30. The greatest pressure of the wind was 36 lbs. on the square foot on March 24, with a velocity of 56 miles in the hour. During the gale of December 22, the greatest pressure recorded was 30 lbs., with a velocity of 50 miles in each of two hours.

The number of hours of bright sunshine recorded during the twelve months ending 1895 April 30 by the Campbell-Stokes instrument was 928 out of the 4454 hours during which the sun was above the horizon, so that the mean proportion of sunshine for the year was 0·208, constant sunshine being represented by 1. In the corresponding period for 1893-4, the number of hours of sunshine was 1364, and the mean proportion of sunshine was 0·306.

The rainfall in the year ending 1895 April 30 was 24·56 inches, which is very nearly the same as the average amount for the 50 years 1841-1890. The number of days on which rain fell was 187.

THE FIELD COLUMBIAN MUSEUM.

THE museum founded to commemorate the World's Columbian Exposition at Chicago has reached a stage which enables it to commence a series of publications designed to present to the world the results of research conducted under its auspices. The first of this series is before us, and is devoted to an historical account of the movement that resulted in the establishment of the museum. From this description we extract the following sketch of the early history of the museum, and of the general character of the contents.

The formation of a museum at Chicago, after the Columbian Exposition, was suggested by Prof. Putnam in 1890, and received the support of Prof. Goode, Director of the U.S. National Museum, Prof. Wilson, of the Smithsonian Institution, and other representative men. In the summer of 1893, a number of the prominent citizens of Chicago resolved "to establish in Chicago a great museum that shall be a fitting memorial of the World's Columbian Exposition, and a permanent advantage and honour to the city." The delicate and important task of securing the funds necessary to carry the resolution into effect was at once begun, but the appeal at first met with little response. A munificent gift from Mr. Field gave confidence in the assured prominence and success of the museum. Mr. G. M. Pullman followed with a subscription of 100,000 dollars, and a like sum was contributed by Mr. H. N. Higinbotham. Mrs. M. D. Sturgis gave 50,000 dollars, and a number of other donations for various amounts were made, as well as Exposition stock having the approximate par value of 1,500,000 dollars. With these funds in hand, the museum committee felt justified in making extensive purchases, including the exhibits from Paraguay, Peru, Java, Samoa, the Hagenbeck collection, and the Ward collection of natural history, for which a sum of 95,000 dollars was paid. The new President of the museum, Mr. E. E. Ayer, presented the Ayer anthropological collection, valued at 100,000 dollars, to the museum, and other donations of material followed. Many exhibits were purchased at the close of the Exposition, and these furnished the broad foundation upon which the present collections have been built. Great gaps in the continuity of separate subjects have thus been, to a large degree, obviated, until

The Field Columbian Museum.

to-day, from one end of the museum to the other, can be traced the story of nature and of man and his works.

The collections illustrating geology in the museum are grouped into Systematic Geology and Economic Geology. In the former division there are about five thousand palæontological specimens, many of them especially instructive and valuable, and as many specimens of minerals, classified according to the chemical constitution of each species. The collection of meteorites in the same division includes several very large specimens, notably the meteoric stone from Phillips County, Kansas, weighing 1184 lbs.; two masses weighing respectively 465 and 344 lbs., with several smaller ones from the meteorite of the Kiowa County, Kansas; two masses weighing 1013 and 265 lbs. respectively, and several smaller ones of the Cañon Diablo, Arizona, meteorite; about 650 individual aerolites of the Winnebago County, Iowa, fall, and many other specimens. Physical geography, structural and dynamical geology, and lithology are also well represented in the division of systematic geology.

The collections of the division of Economic Geology were obtained through the Chief of the Department of Mines, Mining and Metallurgy of the World's Columbian Exposition, from exhibits made in that exposition. Being designed to illustrate the practical bearings of the science of geology, they consist chiefly of specimens which show modes of occurrence in nature of minerals having economic importance, and the localities where they may be obtained. In addition to these, however, are

many illustrations of the processes employed in the extraction and treatment of minerals or ores, and of the application of resulting products to human arts and industries.

An immense amount of material, illustrative of the botany and forestry of all parts of the world, came into the possession of the museum at the close of the Exposition. These exhibits are gradually being arranged in geographical sequence, but some time must elapse before all the specimens can be fully identified and labelled.

The Department of Zoology includes all the classes of animals except birds, and six large halls of the museum building are set apart for the specimens belonging to it. The mounted collection of birds in the Department of Ornithology is essentially one of comparative ornithology, in which the bird fauna of the world is represented by some 650 species. North American bird-life is at present only represented by some 150 species out of a possible 825. Among the treasures of which the museum can boast, however, is a pair of the now (probably) extinct Labrador Duck (*Camptolaimus Labradorius*).

The extensive exhibits illustrating the archæology and ethnology of America, brought together by Prof. F. W. Putnam, were transferred to the museum at the close of the Exposition. A number of other very important collections, representing primitive culture in many widely separated regions of the world, were also obtained. Belonging to the Department of Anthropology are psychological and physical laboratories, and collections of cranic casts, &c., illustrating the physical characteristics of man.

During the Exposition a great group of exhibits had been brought together within the Department of Transportation, to illustrate the evolution of the carrying industry, beginning with its inception in remote times, and extending down to the present day. These exhibits were transferred to the museum building, and largely augmented by collections from other departments. All of this material, together with a number of exhibits illustrating other industries of especial importance to civilised man, including ceramics, the textile art, the leather industry, jewellery, &c., have been brought together in a Department of Industries. The collections in this department have been arranged to show, as far as possible, the more important steps which have led to improvement in handiwork, or progress in the invention of those implements, machines, and processes which have proved to be important factors in the world's material development.

Although but a few months have elapsed since the doors of the museum were publicly thrown open, a course of popular lectures have been inaugurated, a publication series established, and several scientific expeditions sent into the field for augmenting its collections. In these and other directions, the Field Columbian Museum appears to be advancing along the path marked out for it, and performing its part in adding to the wealth of Western civilisation and culture.

PRIZE SUBJECTS OF THE FRENCH SOCIÉTÉ D'ENCOURAGEMENT.

THE prizes and prize subjects of the French Société d'Encouragement pour l'industrie nationale, for 1896 and 1897, are described in the *Bulletin* of the Society. The Society's Grand Prize of 12,000 francs will be given this year to the author of the discovery most useful to French industry. The following list shows the arrangements with regard to the prizes of the two succeeding years:—

1896.

Grand medal to the author, of any nationality, of works that have exercised the greatest influence on the progress of French mechanical arts during the preceding six years.

The Henri Giffard prize of 6000 francs for signal services to French industry. The Parmentier prize of 1000 francs for researches tending to improve the material or processes of agriculture and alimentary industries. The Meslens prize of 500 francs for the author of an application of physics or chemistry to electricity, ballistics, or hygiene.

In the section of Mechanical Arts, a prize of 3000 francs is offered for the best motor fed with some commercial oil. Other prizes are: 3000 francs for an engine of from 25 to 100 horse-power, using as a maximum, when working, $7\frac{1}{2}$ kilogrammes of steam per hour and per indicated horse-power; 2000 francs to the manufacturer who first produces, mechanically, linen threads of which at least 100,000 metres go to one kilogramme, or, in the case of hemp, 15,000 metres per kilogramme; 2000 francs for an investigation, or a method tending to prevent, or at least reduce in amount, the leakages, known as "fuites aux tubes," in marine boilers; 1000 francs for the best memoir on the cost price of the motive power of steam; 2000 francs for a small motor suitable for a home workshop, and which will work by the use of some simple power available in the house, or by energy transmitted from a central station; 3000 francs for improvements in the processes of retting linen and hemp in industrial use.

The prizes offered in the section of Chemical Arts are: 1000 francs for the utilisation of waste products; 2000 francs for a work or memoir of use to chemical or metallurgical industry; 2000 francs for an experimental study of the physical or mechanical properties of one or more metals or alloys, selected from those which are in current use; 2000 francs for a new process for the production of fuming sulphuric acid, or sulphuric anhydride; 2000 francs for an improvement in the manufacture of chlorine; 1000 francs for the discovery of a new alloy useful to the arts; 2000 francs for a scientific study of combustion in the furnaces used for the production of gas; 2000 francs for an investigation of the expansion, elasticity, and tenacity of ceramic clays and coverings; 1000 francs for the substitution of sulphuric acid in dyeing, and especially in silk dyeing, by another compound which will give to the fibres the desired stiffness, without exercising any destructive action; 2000 francs for an investigation of the physical and mechanical properties of glass; 2000 francs for the discovery of processes capable of yielding, by certain chemical changes, useful organic products, such as quinine, cane-sugar, &c.; 2000 francs for an investigation on an industrial process of which the theory is but imperfectly known; 2000 francs for the production of cast steel or iron having useful properties, by the incorporation of a foreign substance.

In Economic Arts the following are the prizes and subjects. A prize of 2000 francs for the invention of a new process in which at least 0·800 kilogrammes of petroleum can be used without danger, as a source of light or heat, either in industry or in domestic economy; 2000 francs for the discovery of methods to diminish the number of chimney fires, and reduce the damage which results from them; 2000 francs for an incandescent electric lamp of one-tenth candle power when a current of 0·05 ampere is passing through it at a potential of 100 volts.

In Agriculture the prizes and subjects are as follows:—2000 francs for the best investigation of the comparative physical and chemical constitution of the soils of one of the natural or agricultural regions of France; 1500 francs for the best varieties of barley for brewing; 3000 francs for the re-establishment of vineyards on chalk soils; 1500 francs for the introduction and culture, on a large scale, of a new forage plant; 2000 francs for the best study of the culture of the vine in various regions of France, and of the influence of various processes of vinification on the quality of wine.

A prize of 1000 francs is offered for the discovery of a plastic material, similar in appearance to some stone, marble, or brick, and hard enough to be used either for the insides or the outsides of houses; 1000 francs for the discovery of a process to prevent woods used by carpenters and cabinet-makers from deformations by atmospheric influences; 1000 francs for the author of the best memoir on some practical process other than a chemical process, and capable of being applied in the workshop, for the detection of adulterated Portland cement.

1897.

A prize of 2000 francs is offered for improvements in the methods of grinding grain; and a prize of 2000 francs for a motor weighing less than fifty kilogrammes per horse-power. This prize is offered with the idea of furthering the problem of aerial navigation. A second prize, having the same object, is for a study of the coefficients necessary to the mechanical calculation of an aerial machine. There is also a prize of 3000 francs for improvements in the manufacture of permanent magnets; and prizes of 3000 francs for an investigation of alcoholic ferments, and 2000 francs for the best investigation of the deterioration of cider, and the means to prevent the changes to which the loss of vivacity is due.

The prizes are open to investigators of any nationality, but the memoirs, and descriptions of inventions, should be written in French. Models, memoirs, descriptions, and specimens intended to compete for prizes must be sent to the Secrétariat de la Société d'Encouragement pour l'industrie nationale, 44 rue de Rennes, Paris. Competitors for the prizes of 1896 must send in before the end of the present year; the latest time for entering memoirs, &c., for the 1897 competition is the end of 1896.

RECENT GLACIAL STUDIES IN GREENLAND.[1]

DURING the summer of 1894, Mr. Chamberlin was enabled to devote some time to a personal study of the glaciation of Greenland, and the results of his observations are so interesting, that all geologists who seek to interpret the records of the "Great Ice Age," will gladly make acquaintance with them. Seldom has a geologist so experienced in the study of glacial drifts and of the problems connected with them, had the advantage of examining the behaviour of ice in the Arctic regions.

His observations were specially directed to the way in which a glacier gathers up detritus along its course, to the way in which it carries it forward and finally puts it down. The main problem he sought to solve, was connected with the basal material of glaciers, débris which, of course, is largely concealed.

In comparing the glaciation of Greenland with that of the mainland of North America, he had to bear in mind, that for the most part the continental drift is spread over a vast plain. In Greenland the ice-fields rest mainly on plateaus fringed by rugged mountains, and he sought for a tract free from such bordering elevations. This was found at Inglefield Gulf, where the borderland is a plateau about 2000 feet above sea-level, and where the margin of the great ice-sheet may be studied on relatively smooth ground, on undulating ground, and in lobes or tongues that descend the valleys. Of the thirty or forty glacial tongues which descend towards Inglefield Gulf, less than one-third reach the shore, and scarcely one-half of these discharge notable icebergs. The majority terminate in valleys whose bottoms are formed of glacial débris, and whose lower gradients are moderate.

The fact that great part of Greenland appears to consist of ancient gneissic rocks, renders the débris more or less stony and arenaceous; clayey material is rare. About Inglefield Gulf, however, the older rocks are covered by thick layers of sandstone and shale, traversed by basic igneous dykes. Hence it is possible there to tell how late the erratics from this sedimentary series were introduced into the ice, to ascertain what courses they pursued, and the actions they suffered.

The margins of the Inglefield glaciers rise abruptly like escarpments of rock, 100 or 150 feet or more. The layers of ice are cut sharply across, exposing their edges; and the formation of these scarps is attributed to the lower inclination of the sun's rays, which strike vertically and effectively against the edges of the glacier, whereas its back is affected only by rays of low slant.

The stratification of the glaciers attracted particular attention. The ice was found to be almost as distinctly bedded and laminated as a sedimentary rock. The vertical face was seen usually to present two great divisions an upper tract of thick, obscurely laminated layers of nearly white ice, and a lower laminated tract discoloured by débris. At the base there is usually a talus-slope, and sometimes there is a moraine. In the lower portion of the ice there are, here and there, interstratified layers of sand and silt, rubble and boulders. These vary from a mere film of silt to a heterogeneous mixture of débris and ice several feet thick. The detritus is usually arranged in definite and limited horizons, the ice above and below being firm, clean, and pure. Often a fragment of rock, or a boulder of considerable dimensions, will be several times thicker than the silt layer, and it projects above and below into the clean ice. The débris-layers, though often regular and persistent, frequently thin out and disappear. Lenses of débris also appear, and the layers are sometimes doubled back upon themselves.

The laminæ of the ice are sometimes very symmetric, straight, and parallel, but often wavy and undulating. In many instances they are greatly curved or contorted. Thus, as Dr. E. von Drygalski has remarked, they closely simulate the foliation and contortion of gneiss.

The débris-belts, which are essentially parallel to the base of the glacier, are confined chiefly to the lower 50 or 75 feet, but they occur up to 100 feet and, perhaps, to 150 feet. They are more abundant at the sides of the lobes than in the centre; a notable portion of the débris having evidently been introduced after the lobes were formed. Thus the detritus appears most abundant in glacier-lobes which descend as cataracts, or crowd between closely hugging cliffs.

In meeting obstacles the basal beds of the glacier sometimes simply curve upwards, carrying their débris with them over the obstacle; at other times, the laminæ of ice are much crumpled. Not only are the foliations of the ice twisted, but they are at times fractured and faulted, and along the fault-plane the laminæ are affected by "drag," as in faulted rocks.

The general stratification of the ice had its initial stages in the original snow-falls; and the seasons doubtless developed annual subdivisions. The more definite partings and the introduction of the layers of débris, arose through a shearing movement between the layers of ice.

The actual process of intrusion of detritus was observed in proximity to a large boss of rock which, protruding through the margin of the ice, had been partially cut away. Trains of débris, apparently rubbed from the surface of the rocky dome, were carried out almost horizontally into the ice in its lee. Some of these were short, while others extended several rods into the ice, passing into the body of it instead of following its base. At one point the overthrust of the ice reached such a degree as to carry the earthy layers obliquely across the thickness of the glacier, producing a marked unconformity.

In another instance similar features were observed below an ice-cataract. Tongues of débris, having their origin in the boulder-clay below the glacier, were seen to reach out into the basal portion of the ice as though they were being introduced into it by the differential movement of the layers upon each other. Thus when the ice is forced over a prominence it settles down a little in its lee, and is then protected somewhat from the thrust of the ice behind. The next ice that passes over, being prevented by the former portion from settling down at once, is thrust forward over it. This is accomplished by the bending and doubling of the layers, and also by distinct shearing. At length, however, the first layer is compelled by the general friction to move somewhat forward, and in time to join the common moving mass, carrying the overthrust layer of débris between it and the ice-layer above.

It appears obvious that the ice in the lee of a rocky prominence moves more slowly than that above; hence the doubling of the laminæ upon themselves. Moreover, there is a gradation from laminæ that simply suffered doubling up, to layers that obviously sheared upon each other and produced manifest unconformity by overthrust.

Evidence showed that the more solid (blue) bands in the ice are produced by exceptional pressure in moving over rugosities, and that their position in the ice is parallel to the ice-movement; while at the same time blue bands may be developed nearly at right-angles, after the manner of slaty cleavage.

Summarising the above conclusions, it appears that stratification originated in the inequalities of deposition, emphasised by intercurrent winds, rains, and surface meltings; that the incipient stratification may have been intensified by the ordinary processes of consolidation: that the shearing of the strata upon each other still further emphasised the stratification, and developed new horizons under favourable conditions: that basal inequalities introduced new planes of stratification, accompanied by earthy debris, and that this process extended itself so far as even to form very minute laminæ.

There is involved in the foregoing conceptions the idea of an ice-layer acting as a unit of movement: at any rate, there is recognised individuality of movement in the layer. This view involves the idea of rigidity rather than viscosity. The introduction of earthy material into the ice-layers involves the idea of thrust rather than pull. The picture is not that of gravitation pulling a thick, stiff liquid down the lee side of a rocky prominence, but of a rigid body thrusting itself over the crest by means of a force in the rear.

The extreme fragility of the ice is difficult to harmonise with the idea of viscosity. Wherever the ice passed over an undulation of even moderate dimensions, it was abundantly crevassed. There was no indication that boulders descend through the ice as heavy substances descend through viscous bodies. The rigidity did not prevent contortions and foldings of the laminations, such as take place in crystalline rocks, but faulting and vein-structures also occur; and there seems no more occasion to assume viscosity in the one case than in the other. Even if a certain measure of viscosity be admitted, it does not follow that viscosity was an essential agency of motion. The crystalline body may readily be made to change its form by the removal of particles from one portion by melting, and their attachment at other points by congelation; but not, apparently, by the flowing of crystallised particles over each other in their crystalline conditions.

It has been already pointed out that much basal material is

[1] Abridged from a paper by T. C. Chamberlin, in the *Bulletin* of the Geological Society of America, February 1895.

carried in the lower layers of ice. It was also a matter of frequent observation that débris lies under the ice. Apparently the ice sometimes pushes this along, and sometimes slides over it. At the end of the glacier the debris within the ice is freed by melting, and accumulates as a talus-slope. This sometimes protects the basal layers from melting, and they become at length incorporated in the growing accumulation.

It appeared, from the stages presented by the several glaciers, that where the ice is slowly advancing, the talus-slope gradually grows forward and constitutes an embankment, upon which the glacier advances. It thereby grades up its own pathway in advance. On seeing this process, one is at no loss to understand how ice can advance over fields of sand or soil without in any way disrupting them. It buries them before it advances upon them.

Where the frontal material accumulates in a large mass, it opposes such a degree of resistance to the ice that its layers are curved upward on the inner slope; and if the glacier subsequently advances, the ice rides up over the moraine. Several such instances were observed, but none was seen where the ice showed any competency to push even its own débris, in notable quantity, in front of it. The ice is weaker than the moraine as a whole.

Great quantities of snow are carried by winds from the region of the great ice-cap, and this snow may be lodged in immense heaps in the lee of the terminal moraines. Such a border-drift may have a breadth of from 1000 to 3000 feet. It becomes solidified after the fashion of a glacier, and may serve to arrest or deflect the main ice; for it was observed that the basal layers of the ice in places curved upwards on encountering the resistance of this wind-drifted accumulation.

The rate of movement of the majority of the glaciers was found to be exceedingly slow, though a few which produce large icebergs are notable exceptions.

The amount of drift on the territory once occupied, but now free from ice, was scanty. At some points there are considerable accumulations of drift within a mile or two of the present ice-front, but over much of the area no great moraines, nor any thick mantles of drift, were to be seen. There was but moderate evidence of glacial action; the land was gently rounded, but not greatly moulded. In this area of Southern Greenland tracts of angular, unsubdued topography alternate with rounded, flowing contours. The inference was drawn that the ice formerly so extended itself as to reach the present coast for about half its extent, while in the remaining portion the ice fell short. Thus the conclusion seems unavoidable that the ice of Greenland, on its western side, at least, has never advanced very greatly beyond its present border in recent geologic times. This carries with it the dismissal of the hypothesis that the glaciation of the mainland of North America had its source in Greenland.

There is no ground to question the former elevation of Greenland, but it would appear that this was not coincident with conditions favouring glaciation. H. B. W.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD. Among the distinguished men upon whom it is proposed to confer the honorary degree of D.C.L., on June 26 are Sir W. H. Flower and Prof. Michael Foster.

In a Convocation held on Tuesday, the statute appointing Dr. E. B. Tylor professor of Anthropology during the tenure of his office as Reader in Anthropology was finally approved. In a Congregation, held on the same date, the Statute on Research Degrees received the final approval of the house, and it now remains for it to be passed by Convocation. The proposed Final Honour School of Anthropology was again brought before Congregation, and excited some opposition. On a division the proposed statute was carried by a considerable majority, the numbers being: Placet, 47; Non placet, 28. The statute has now to run the gauntlet of Convocation before it finally passes into law. In the same Congregation, the dates of the preliminary examinations in the Honour Schools of Natural Science were fixed for the Monday after the eighth week of Full Term in Hilary Term in each year, instead of in the last week or last week but one, as has hitherto been the custom; and the grant of £300 per annum to the Chemical department of the University Museum was renewed for a period of five years. The published lists of the candidates for the final and preliminary examinations in Natural Science show that there are 44 candidates in the final school and 64 candidates in the preliminary school. These figures do not include women students.

CAMBRIDGE.—The following is the speech delivered by the Public Orator, Dr. Sandys, on May 30, in presenting for the honorary degree of Doctor in Science, Dr. John Murray, editor of the *Challenger* publications.

Meministis omnes poetae nostri maximi locum insignem, ubi Northumbriae Ducis filius acerrimus non recusavit gloriam aut ex ipsa luna audacter deducere, aut maris in profundo demersam extrahere, modo solus sine rivali laudem omnem sibi vindicaret. Quanto pulchrius autem rerum naturae penetralia intima assidue perscrutari, eque oceani altitudine immensa laudem cum sociis optimis participatam reportare. Adest unus ex illis qui, plusquam tribus annis in oceano explorando fortiter toleratis, ut poetae antiqui verbis sensu novo utar,

"referebant navibus altis
occulta spolia, et plures de pace triumphos."

Una saltem nominis bene ominati navis velut ipsam rerum naturam ad certamen provocavit, ipsamque veritatem in profundo abstrusam orbi terrarum patefecit. Tanti autem itineris monumenta, quinquaginta voluminum in serie ingenti a collegis plurimis parata, viri huiusce praesertim industria infinita non modo adaucta et summatim descripta sed etiam ad terminum felicem perducta et diei in lucem prolata sunt. Quid non potuit rerum naturae, quid non potuit veritatis amor?

"Merses profundo; pulchrior evenit."

Duco ad vos Universitatis Edinensis alumnum, oceani indagatorem indefessum, virum etiam in posterum sine dubio laudem indies maiorem meriturum, IOANNEM MURRAY.

The Master of Downing (Dr. Hill) and Dr. Barclay-Smith will give a course of instruction in Practical Histology during the Long Vacation, beginning on July 6.

The State Medicine Syndicate propose to make a grant of £50 to the Department of Pathology, in aid of the course of laboratory instruction in Bacteriology therein provided for candidates for the diploma in Public Health.

Prof. Ewing's serious illness has made it necessary to appoint Mr. Dalby, Demonstrator in the Engineering Laboratory, to act as Examiner for him in the Mechanical Sciences Tripos.

The Smith's Prizes in Natural Philosophy have been awarded (1) to G. T. Manley, of Christ's College, for his essay on "The Conformal Representation of a Quadrilateral on a Half Plane," and (2) to G. H. J. Hurst, of King's College, for his essay on "Electro-magnetism and Magneto-optic Rotation." Mr. Manley and Mr. Hurst were respectively Senior and Second Wrangler in 1893. The essays of H. E. Atkins, of Peterhouse, and P. E. Bateman, of Jesus College, are declared worthy of honourable mention. Mr. Atkins was bracketed Tenth Wrangler, and Mr. Bateman bracketed Fifteenth Wrangler in the same Tripos.

Mr. S. S. Hough, of St. John's College, has been elected Isaac Newton Student in Astronomy for the three years ending June 15, 1898.

Mr. Charles Chree, Director of the Kew Observatory, has been approved for the degree of Doctor of Science.

Mr. W. N. Shaw has been appointed Chairman of the Examiners for the Mechanical Sciences Tripos, in the room of Prof. Ewing, who has resigned on the ground of illness.

Mr. Charles Smith, Master of Sidney Sussex College, has been elected Vice-Chancellor for the ensuing academical year.

Classes in Osteology, in General Chemistry, in Geology, and in Experimental Physics, are announced to be held in the Long Vacation.

Mr. A. E. Shipley, University Lecturer in Invertebrate Morphology, has been appointed a member of the University Press Syndicate.

PROF. W. T. A. EMTAGE, of University College, Nottingham, has been elected Principal of the Technical Institute, Wandsworth.

HONORARY degrees were conferred, by the Chancellor of Victoria University, last week, upon Lord Kelvin and Sir Henry Roscoe, among others, for distinguished services rendered to the University.

THE twelfth annual report of the Mitchell Library, Glasgow, is before us. The library is open to the public, and is adminis-

tered by a committee of the Glasgow Town Council, from which it obtains a grant of £2000 a year, from the moneys received under the Local Taxation (Customs and Excise) Act; it is also fortunate in being the recipient of several bequests from persons interested in its work. A noteworthy point is that, out of a total of 112,447 volumes contained in the library, no less than 20,812 are classified under "Arts, Sciences, Natural History." This is two thousand volumes more than are included under any other head. The most important accession to the library during the three years covered by the report (1892-94) consists of a complete set of the *Transactions* of the Royal Society, in 183 volumes. A very valuable addition to the scientific resources of the library has resulted from agreements entered into with the Glasgow Natural History Society, and with the Glasgow Geological Society. These societies have transferred to the library their sets of the *Transactions* and *Memoirs* of foreign scientific societies, the Library Committee undertaking on their part to continue to the members their privilege of borrowing the books, to bind such as required it, and to bear the expenses attending the printing extra copies of the *Transactions* of the Glasgow societies, and forwarding the same to the foreign societies as an exchange. During last year, 115,788 scientific works were issued, the daily average being 386. It would be well if there were more public libraries conducted on the enlightened plan of the Mitchell Library.

ANOTHER library of which we have received the report (in this case the first report) is that of St. George, Hanover Square. Though on a much smaller scale than the Mitchell Library, the Commissioners appear to aim at making the library a means of education as well as of recreation. There are 11,860 volumes in the lending library, of which twenty per cent. are fiction, and 6206 in the reference library, none of which are novels. To obtain a satisfactory conclusion as to the work of a library, the use made of the library as a whole, and not of any particular department, ought to be taken into account. The records of the institution show that out of 416,760 visitors during the year, only thirteen per cent. of the readers went for the purpose of borrowing works of fiction from the lending library. A noteworthy feature in connection with the library is a museum of objects arranged as an elementary and self-explanatory collection, as an introduction to larger museums of natural history.

IT is proposed to hold a Technical Education Conference at the Society of Arts on June 20. The Society has addressed a letter to Technical Education Committees, asking them to send delegates to the Conference. Among the subjects to be considered is the "lack of a central organisation which might deal especially with such questions as the examination and inspection of classes. In spite of the valuable work which has been done by the City and Guilds of London Institute, and by other bodies, it is only in a portion of the subjects sanctioned as subjects of technical instruction that examinations are held. The wide field of agriculture and home industries is untouched; while no means are provided for anything like a general system of inspection which local authorities may call to their aid should they desire to do so." There are also other points with regard to which common action would be desirable, and it is hoped that by bringing together those who are interested in technical education the best way in which the Society can enlarge the scope of its present action in connection with the subject will be found.

THE Technical Instruction Committee of the Essex County Council have arranged for a short course of elementary instruction in horticulture, to be given at the County Technical Laboratories, Chelmsford, during the first three weeks in July. The course of study is intended to give sound elementary instruction in the cultivation of plants, based upon a knowledge of plant physiology. The teaching throughout will be practical; every lecture will be abundantly illustrated and immediately followed by demonstrations and individual practical work by the students themselves.

SCIENTIFIC SERIALS.

Internationales Archiv für Ethnographie, Band viii. Heft ii.—On the ethnography of Matty Island, by Dr. F. von Luschan. Although Matty is a small island, about ninety-three miles north of German New Guinea, between 142° and 143° E. long., Dr. von Luschan comes to the conclusion that the natives are not Melanesians; they are much lighter than almost any Melanesians, some being of a deep red flesh colour, eyes slit-like, nose narrow, hair black and in long locks. Of the thirty-eight weapons and utensils in the Berlin Museum not one can with certainty be allocated to any known culture-mixture; any Micronesian resemblance is purely superficial. It seems probable that the people have remained isolated for at least 300 years. Three plates of utensils, &c., illustrate the paper.—Dr. O. Schellong's note on some Melanesian drawings is illustrated by two coloured plates, and is supplemented by some notes by J. D. E. Schmeltz. The drawings are interesting as showing how unlike the objects intended native delineations may be. It is to be hoped that more illustrations of this aspect of the art of savages will be forthcoming. Of the notices of recent publications, those on "Arrow-poison" and "Ethnological Botany" are especially interesting.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 2.—"Alternate Current Dynamo Electric Machines." By J. Hopkinson, F.R.S., and E. Wilson.

The paper deals experimentally with the currents induced in the coils and in the cores of the magnets of alternate current machines by the varying currents in and the varying positions of the armature. It is shown that such currents exist, and that they have the effect of diminishing to a certain extent the electromotive force of the machine when working on resistances as a generator without a corresponding effect upon the phase of the armature current. It is also shown that preventing variations in the coils of the electromagnet does not, in the machine experimented upon, greatly affect the result, and that the effect of introducing copper plates between the magnets and the armature has not a very great effect upon the electromotive force of the armature, the conclusion being that the conductivity of the iron cores is sufficient to produce the main part of the effect. A method of determining the efficiency of alternate current machines is illustrated, and the results of the experiments for this determination are utilised to show that in certain cases of relation of phase of current to phase of electromotive force, the effect of the local currents in the iron cores is to increase, instead of to diminish, the electromotive force of the machine.

May 9.—Bakerian Lecture: "On the Laws of Connexion between the Conditions of Chemical Change and its Amount." By A. Vernon Harcourt, F.R.S., and William Esson, F.R.S. "III. Further Researches on the Reaction of Hydrogen and Dioxide and Hydrogen Iodide."

In this paper are considered the effect upon the reaction of (1) substances not directly participating in reaction, (2) temperature.

The general conclusion as to the effect of the medium upon the reaction is expressed as follows:

Each constituent of the medium produces an effect on the rate of change of unit peroxide and unit iodide, proportioned to the mass, and varying with the nature of the constituent. The increment of this rate per unit mass of each constituent is constant so long as the quantity of the predominant constituent present in the medium is sufficiently large, in comparison with the other constituents of the medium, to render the media in successive experiments practically homogeneous. For example, when the ratio of the numbers of H^2SO^4 and HI in the medium exceeds 20, the formula for the rate at a given temperature is

$$\alpha = i\{a + b(i-1) + ds\},$$

a being the theoretical rate with unit of HI, b the increment per unit of hydrogen iodide per unit of iodide, and d the increment per unit of hydrogen sulphate per unit of iodide. If the ratio falls below 20 the formula is

$$\alpha = i\{a + b'(i-1) + d's\},$$

in which b' and d' depend upon the relative masses of sulphate and iodide present in the medium.

Variation of Temperature.

The discussion of the numerous experiments made at temperatures ranging from 0° to 50°, in media in which the quan-

tities of iodide range from 3·64 HI. to 23 HI. the quantities of hydrogen sulphate from 45 H^2SO^4 to 408 H^2SO^4, and the quantities of hydrogen chloride from 70 HCl to 547 HCl, leads to the following law of connexion between chemical change and temperature.

If α_1 is the rate of chemical change at a temperature $t_1°$ in a homogeneous medium consisting of given constituents per unit volume, and α_2 is the rate at a temperature $t_2°$ in the same medium, the ratio of α_1 to α_2 is $\{(273 + t_1)/(273 + t_2)\}^m$, m being a constant depending upon the character of the constituents of the medium. When the temperatures are measured from the absolute zero − 273°, and are denoted by T_1, T_2, the formula assumes the simpler form,

$$\alpha_1/\alpha_2 = (T_1/T_2)^m.$$

The constancy of the value of m for a particular medium is secured when the quantity of the predominant constituent of the medium is sufficiently large in comparison with the quantities of the other constituents to make the medium practically homogeneous. When this is not the case the value of m has some value intermediate to the values which it has when one or other of the constituents is sufficiently predominant to secure a constant value.

In media in which hydrogen sulphate is sufficiently predominant, the value of m is 20·38; similarly for hydrogen chloride the value of m is 21·17. When the medium consists of water and hydrogen iodide, the value of m is 24·1. The introduction of sodium sulphate in large quantity into a medium otherwise consisting mainly of hydrogen sulphate reduces the value of m from 20·38 to 18·1. In a medium in which the main ingredient is sodium hydrogen carbonate, the value of m is approximately 10.

A further confirmation of the law of connexion between chemical change and temperature is obtained from the discussion of experiments on the rate of change of hydrogen chlorate and potassium iodide made by W. H. Pendlebury and M. Seward. The value of m is in the case of this chemical change 40·5.

It follows from the law enunciated above that at the temperature of absolute zero no chemical change can take place.

If the smallest value of m, viz. 10, is taken, a chemical change, which is completed in one minute at a temperature zero, would require for its completion, at a temperature of −200°, a little more than a year. If 20 is taken as the value of m, the minute would be increased to more than half a million of years by the same reduction of temperature.

The law enunciated above may also be stated in the following form.

The increment of each unit of chemical change due to a rise of temperature varies as the increment of each unit of absolute temperature.

This law is expressed by the formula

$$D\alpha/\alpha = mDT/T.$$

Chemical Equilibrium.

A case of equilibrium between the reactions

$$H^2O^2 + 2HI = 2H^2O + I^2,$$
$$2H^2O + I^2 = H^2O^2 + 2HI.$$

leads to a discussion of the general equations of chemical equilibrium, which is given in an appendix to the paper. These equations are employed to interpret the results of experiments published by Dr. Gladstone in the *Transactions* of the Royal Society (*Phil. Trans.*, vol. clxv.). They had been previously applied to the case of chemical equilibrium investigated by Prof. Dixon, in a paper published in vol. clxxv. of the *Transactions* of the Royal Society, the reactions in that case being

$$H^2O + CO = H^2 + CO^2,$$
$$H^2 + CO^2 = H^2O + CO.$$

Physical Society, May 24.—Captain W. de W. Abney, President, in the chair.—Dr. Kuenen read a paper entitled "On the condensation and the critical phenomena of mixtures of ethane and nitrous oxide." If the vapour of a pure substance is compressed at constant temperature, then when a certain pressure is reached the vapour commences to condense, and the pressure remains constant until all the vapour is liquefied. Taking the pressure and temperature as coordinates the corresponding temperatures and pressures at which liquefaction takes place are plotted, the curve obtained is called the vapour pressure curve, and this curve ends at the critical temperature and pressure of the given substance. On the other hand, if a mixture of two vapours is compressed at constant temperature the pressure no longer remains constant while condensation is taking place, but gradually rises. The points at which condensation commences and ends lie on a U-shaped curve having its vertex turned towards the direction of increasing temperatures. Such a curve the author calls a "border curve." The point at which a line parallel to the axis of p touches a border curve corresponds to the critical point (R) of the given mixture. For all temperatures higher than that corresponding to R there is no condensation into liquid possible, while for any temperature below the critical temperature there are two vapour pressures, one corresponding to the commencement, and the other to the conclusion of liquefaction. The envelope of all the border curves for mixtures containing different proportions of the two bodies is a curve, called the plait-point curve, joining the critical points of the two constituents. The point of contact (P) of a border curve with the plait-point curve corresponds to the plait-point on van der Waal's, thermodynamic surface. If when we go along the border curve, starting from its lower branch, we first reach R and then P, and if we indicate the temperatures corresponding to P and R by T_P and T_R, then for temperatures between T_P and T_R as the pressure is increased the quantity of liquid firts increases, reaches a maximum, and after that decreases till it disappears. This is called retrograde condensation of the first kind, and has been observed by the author in the case of mixtures of methyl chloride and carbon dioxide. If P, however, lies beyond R the process of condensation for temperatures between T_P and T_R is different. In this case the volume of vapour increases, reaches a maximum, and then decreases. This constitutes retrograde condensation of the second kind. It was with a view to the experimental observation of this second kind of retrograde condensation that the author undertook his observations. A series of observations were made with each of the pure gases, and gave the following values for the critical temperature:—

Ethane	32°·3 C.
Nitrous oxide	36°·1 C.

In the case of the mixtures, the very interesting result is obtained that the critical temperature is in some cases less than that of either of the constituent gases. Thus a mixture containing 10 per cent. of C_2H_6 has a critical temperature of 32°, the same critical temperature as for pure ethane. All mixtures containing more than 10 per cent. of ethane have a lower critical temperature than 32°; the lowest critical temperature obtained is 25°·8, and belongs to a mixture containing equal volumes of ethane and nitrous oxide. Another important point is that the border curves do not all lie between the vapour pressure curves of ethane and nitrous oxide. Hence for any temperature there is some mixture which gives a maximum vapour pressure. It also appears from the curves, given in the paper that the maximum vapour pressure is obtained with almost the same mixture at all temperatures, and that this maximum vapour pressure does not disappear with increase of temperature, but remains even up to the critical region. For mixtures containing between 20 and 50 per cent. of C_2H_6 retrograde condensation of the second kind takes place, but the author has not been able to observe it, since the difference between T_P and T_R for the two substances experimented on cannot be more than 0°·1, and the temperature could not be maintained sufficiently constant to hope to be able to detect any phenomenon taking place over such a small temperature range. The author showed his arrangement for stirring the liquid and vapour in the experimental tube so as to prevent any retardation of the different phases due to slow diffusion in the long narrow tubes employed. A small piece of iron with enamel beads on the ends is enclosed in the experimental tube, and by means of a small magnetising coil which surrounds the jacket used to keep the temperature of the tube constant, this piece of iron can be moved up and down the tube so as to keep the liquid and vapour thoroughly stirred. Prof. Carey Foster and Prof. Ramsay complimented the author on the very lucid way he had expounded a by no means easy subject. Dr. Sidney Young congratulated the author on the able use he had made of his lucky discovery of two bodies such that their mixture should have a lower critical temperature than that of either of the pure substances. Prof. Ramsay and he (Dr. Young) had made experiments on the vapour pressure of mixtures of alcohol and ether, and had found great difficulty in pre-

venting the separation of the components when the volume was altered, and he could, therefore, thoroughly appreciate the utility of the author's device for overcoming this difficulty. They had also experienced considerable difficulty in filling the tube with a mixture of known composition and free from air, and he considered that when dealing with mixtures it was better to employ gases, although they could not be obtained in so perfect a state of purity as liquids, on account of the greater ease with which a mixture of known composition can be obtained. The plan of making separate observations on the pure substances was a good one, and considering that the author measures the increase of pressure during the process of condensation, so that any air which happened to be present produced the maximum effect, the small rise in pressure obtained indicated a high degree of purity in the gases employed. He would like to ask the author if in the case of mixtures he found it possible to determine accurately the point where condensation commenced and ended, for with the alcohol and ether mixtures they had found it very difficult to determine these points. He also hoped the author would continue his observations in the direction indicated in the paper. Mr. Inwards suggested that in the case of liquids which act on iron, the iron stirrer could be enclosed in glass or india-rubber. It might also be possible to obtain more efficient stirring by means of a small fan or propeller worked by an electro-magnet rotating outside the tube. The author, in his reply, said that when the mixtures were well stirred, the pressures at which condensation commenced and ended were well marked.—Mr. Burstall commenced the reading of a paper on the measurement of a cyclically varying temperature. The experiments were undertaken with a view of measuring the temperature inside the cylinder of a gas engine at different points of the stroke of the piston. A modified form of platinum thermometer is employed to measure the temperature, and since the variations in temperature are extremely rapid, the wire had to be very thin and unprotected by any covering such as is ordinarily employed. The leads of the thermometer pass through a slate plug fixed in a seamless steel tube, asbestos being used as a packing to prevent leakage. The resistance of the thermometer is measured by means of a Wheatstone's bridge. Since the temperature at a certain part only of the *working* stroke had to be measured, the galvanometer circuit was broken in two places; one of these breaks was closed by means of a cam on the shaft of the engine at a given point of each revolution, while the other was closed when an explosion took place by means of a relay worked by the pointer of a steam engine indicator attached to the cylinder of the engine. The remainder of the paper was postponed till the next meeting.

Linnean Society, May 24. Anniversary Meeting.—Mr. C. B. Clarke, President, in the chair.—The Treasurer presented his annual report, duly audited, and the Secretary having announced the elections and deaths during the past twelve months, the usual ballot took place for new members of Council. The following were elected:—Prof. J. B. Farmer, Mr. A. Gepp, Prof. Howes, Dr. St. G. Mivart, and Mr. A. S. Woodward. On a ballot taking place for the election of President and officers, Mr. Charles Baron Clarke was re-elected President, Mr. Frank Crisp Treasurer, Mr. B. D. Jackson Botanical Secretary, and Prof. G. B. Howes Zoological Secretary. The Librarian's report having been read, and certain formal business disposed of, the President delivered his annual address, prefaced by some remarks on the present position of the Society. On the motion of Sir Joseph Hooker, seconded by Dr. John Anderson, a vote of thanks was accorded to the President, with a request that he would allow his address to be printed. The Society's gold medal was then formally awarded to Prof. Ferdinand Cohn, of Breslau, and was received on his behalf by Mr. B. D. Jackson for transmission through the German embassy. The President having called attention to the retirement of the Zoological Secretary, Mr. W. Percy Sladen, after holding office for ten years, an announcement which he felt sure would be received with universal regret, it was proposed by Mr. Carruthers, seconded by Mr. Crisp, and supported by Mr. Charles Breese—"That the Fellows of this Society, regretting the retirement of Mr. Walter Percy Sladen from the post of Zoological Secretary, which he has occupied for the past ten years, desire to record upon the Minutes of the Society an expression of their high appreciation of the services which he has rendered to the Society, and of the very able manner in which he has at all times discharged the duties of his office." This resolution having been put, was carried unanimously, and after a sympathetic reply from Mr. Sladen, the Society adjourned to June 6. In the evening a number of Fellows of the Society dined together at the Grand Hotel, Charing Cross, the President occupying the chair, and being supported by several distinguished visitors.

Royal Meteorological Society, May 15.—Mr. R. Inwards, President, in the chair.—Mr. G. J. Symons, F.R.S., and Mr. G. Chatterton read a paper on the November floods of 1894 in the Thames Valley, which they had prepared at the request of the Council of the Royal Meteorological Society. This consisted of a systematic description of the causes which led to the great floods of November last, and an analysis of the records obtained from the Thames Conservancy Board, from the engineers of several of the towns along the river, and also from rainfall observers throughout the Thames watershed. The information was given chiefly in the form of tables, one of the first being a chronological history of floods in the Thames Valley from the year 9 A.D. down to the present time. This was followed by a short description of the damage wrought in November 1894, which was illustrated by a number of interesting lantern slides. Details were then given of the levels reached at various places in all the principal floods from 1750 to the present time. The authors exhibited a map showing the relative elevation of all the parts of the Thames basin, and then gave details of the rainfall for each day from October 23 to November 18, 1894. The results obtained by the Thames Conservancy Board, showing the flood levels at each lock, were exhibited on a longitudinal section from Lechlade to Teddington, and the hydraulic inclinations from lock to lock were shown in a tabular form. The volume of flood water, as gauged by the Thames Conservancy at Teddington, rose rapidly from 4000 million gallons per diem on November 12, to 10,250 million gallons on the 16th, 12,800 million gallons on the 17th, and to over 20,000 million gallons on the 18th, when the discharge reached its maximum. The last-named discharge is equivalent to 0·37 inch over the whole watershed of the Thames above Teddington Lock.—Mr. F. J. Brodie read a short paper on the barometrical changes preceding and accompanying the heavy rainfall of November 1894, from which it appeared that the latter half of October was characterised by unusually bad weather, especially in the more western and southern parts of the British Isles. The torrential rains from November 11 to 14, which actually caused the floods, were due to two secondary depressions which developed a certain amount of intensity as they passed over the southern part of England.

CAMBRIDGE.

Philosophical Society, May 13.—Prof. J. J. Thomson, President, in the chair.—Exhibition of some recent photographs of the moon, by Mr. Newall.—On the "volume heat" of aniline, by Mr. E. H. Griffiths. The results of an inquiry (by what may be termed an absolute method) into the influence of temperature on the capacity for heat of aniline were published in the *Philosophical Magazine*, January 1895. During last autumn, Mr. C. Green, of Sydney College, made a series of observations on the *density* of the same compound, over the temperature range 15° to 52° C. Three separate sets of determinations of the density gave very concordant results. If the capacity for heat of equal volumes at different temperatures be denoted by the phrase "*volume heat*," then the "volume heat" at any temperature is the product of the capacity for heat and the density. In the case of aniline, the "volume heat" appears to be constant. Our knowledge of the changes in the capacity for heat of water due to changes of temperature is so uncertain that the *relative* values of the changes in the specific heat of other substances are of little absolute value. The author, therefore, has been unable to extend the inquiry into the "volume heat" of other bodies than aniline, for he has not succeeded in finding any other determinations which do not rest on some assumption as to the behaviour of water.—Exhibition of Goldstein's experiments on kathode rays, by Mr. J. W. Capstick. Mr. Capstick showed Goldstein's experiments on the effect of a stream of kathode rays on salts of the alkalies. When the rays are directed on potassium chloride, for instance, the salt becomes of a heliotrope colour, and retains the colour for several days if kept out of contact with moisture. The effect appears to be due to a chemical change in the substance—probably the formation of a sub-chloride—but the layer of altered salt is so exceedingly thin that it is difficult to get unequivocal chemical evidence as to its nature.—On a curious dynamical property of celts, by Mr. G. T. Walker. Mr. G. T. Walker exhibited celts which

possessed the property of spinning in only one direction upon a horizontal surface. On the formation of cloud in the absence of dust, by Mr. C. T. R. Wilson. The cloud-formation is brought about, as in the experiments of Aitken and others, by the sudden expansion of saturated air. A form of apparatus is used in which a very sudden and definite increase in volume is produced, and in which the possibility of dust entering from the outside seems to be excluded. If ordinary air is started with, it is found that after a comparatively small number of expansions, to remove dust particles by causing condensation to take place on them, there is no further condensation unless the expansion exceeds a certain definite amount. With expansion greater than this critical value condensation invariably takes place, and the critical expansion shows no tendency to rise, however many expansions be made. The latest result for the ratio of the final to the initial volume, when the critical expansion is just reached, is 1·258 (when initial temperature = 16°·7). This corresponds to a fall of temperature of 26° C., and a vapour pressure 4·5 times the saturation pressure for a plane surface of water. The radius of a water drop just in equilibrium with this degree of supersaturation = $6·5 \times 10^{-8}$ cm., assuming the ordinary value of the surface tension to hold for drops of that size.

May 27.—Evaluation of an automorphic function, by Mr. H. F. Baker.—On a construction in geometrical optics, by Mr. J. Larmor. Note on the steady motion of a viscous incompressible fluid, by Mr. J. Brill.

PARIS.

Academy of Sciences, May 27.—M. Cornu in the chair.—On an algebraical problem connected with Fermat's last theorem, by M. de Jonquières. A contribution to the history of the cerium earths, by M. P. Schutzenberger.—On the accumulation in the soil of cupric compounds used in the treatment of parasitic diseases in plants, by M. Aimé Girard. The evidence furnished by the author, in addition to the facts made known by other writers, completely proves that continuous treatment with copper compounds for a long period has no influence either upon the quantity or the quality of the crop obtained from the vine or potato.—Dr. Frankland was elected Foreign Associate of the Academy. Injection of ethyl alcohol into venous blood, by M. N. Grehant. From experiments made on a dog, it is concluded that, after the injection into the blood of a considerable volume of alcohol, the proportion of this substance in the blood five minutes after the injection and for more than eight hours afterwards becomes absolutely constant.—Spectroscopic researches on Saturn's rings, by M. H. Deslandres. The rotation of the planet and of its inner and outer rings has been measured by the methods used first by the author with the planet Jupiter, and employed by Keeler in his recently published researches on the subject of this paper. The author differs from Keeler insomuch as he does not regard this kind of evidence as a proof of the meteoric nature of the rings.—On the reduction of nitric oxide by iron or zinc in presence of water, by MM. Paul Sabatier and J. B. Senderens. The reduction of gaseous nitric oxide or nitric oxide dissolved in ferrous sulphate solution results in the production of nitrous oxide and nitrogen, finally the nitrous oxide is completely reduced also. A small amount of ammonia is formed, and a considerable quantity of hydrogen liberated, when the reaction is permitted to go on for a considerable time.—On the reduction of silica by aluminium, by M. Vigouroux. Silicon obtained in the crystalline form by this process is described.—A study of some reactions of lead sulphide, by M. A. Lodin. Mr. James Hannay's conclusions concerning the hypothetical compound PbS_2O_2, and the part played by it in the metallurgy of lead, are controverted. It is found that lead sulphide fuses at 935°, but exerts a considerable vapour pressure at temperatures much lower; hence the explanation of the volatilisation of galena requires no new compound to be supposed to exist. The long admitted equations expressing the reactions taking place in the reverberatory furnace are completely verified by the author.—On certain phenolic derivatives, by M. A. Béhal.—On crystallised cinchonine, by M. Ferdinand Roques.—Transformation of an amide salt into an amido-acid. Pyruvic acid forms with aniline a condensation product, $CH_3 . C(NC_6H_5) . COOH$. Phenylglyoxylic acid, under the same conditions, forms the salt, $C_6H_5 . CO . COOH . NH_2 . C_6H_5$. On dissolving this in methyl alcohol, the condensation product, $C_6H_5 . C(NC_6H_5) . CO_2H$, separates out in the crystalline form in a few minutes in the cold.—On ozobenzene, by M. Adolphe Renard. By the action of ozone on benzene a white explosive substance is produced having the composition $C_6H_6O_6$.—On the fixation of iodine by potato-starch, by M. Gaston Rouvier.—On the elimination of magnesia in the urine of infants suffering from rickets, by M. Oechsner de Coninck.—On the employment of serum from animals immunised against tetanus, by M. L. Vaillard. The antitetanic serum is able to confer complete immunity for from two to six weeks, but if the tetanus has become established, inoculation is not able to prevent progress of the disease. The toxine in tetanus is perhaps the most active of the bacterial poisons, yet the antitoxine of the serum is even more active.—The relation between relief and the frequency and intensity of earthquakes of any region, by M. de Montessus.—Atmospheric and seismic perturbations of the month of May last and their connection with solar phenomena, by M. Ch. V. Zenger.

MASKELYNE'S CRYSTALLOGRAPHY.

Crystallography, a Treatise on the Morphology of Crystals. By N. Story-Maskelyne, M.A., F.R.S., Professor of Mineralogy, Oxford. 521 pp. and xii. pp., 398 figures, 8 plates, 8vo. (Clarendon Press, 1895.)

AFTER wandering in the desert for considerably more than forty years, the English student of crystallography is at length brought within sight of the promised land; it is true that guides have been offered to him in the interval, but they have spoken in strange tongues, and have sometimes been mere dust-clouds of unnecessary formulæ and notations, calculated rather to bewilder than to lead.

The long-expected treatise of Prof. Maskelyne will be found to fully justify the anticipations with which it has been awaited; those who desire to study crystals and crystallography are no longer confronted by the want of an authoritative handbook, and need no longer lose themselves among the works of foreign authors. The English books hitherto available are few in number. The remarkable "Treatise" and "Tract" of the late Prof. Miller established, in the most rigid manner, a mathematical basis for the science, and must always remain standard works—masterpieces of precision. These two books contain, in a few pages, all that is essential; but being condensed into a bald sequence of theorems, they appeal almost exclusively to the mathematician. Mr. Gurney's little introduction to the subject, and the text-book of the late Prof. G. H. Williams, are excellent stimulants to the beginner, but will not suffice for the more advanced student; the present work supplies most completely what was wanted.

It is easy to state what is required from the practical point of view in a text-book on the morphology of crystals: the learner desires to know what are the forms of crystals, and how they differ from other figures; he must be told how they are determined and described, and for educational purposes it is especially important that the geometrical relations should be established by simple methods of proof from intelligible principles.

All this the present volume satisfactorily accomplishes. A crystal is considered to be, for morphological purposes, a complex of planes which obey a simple geometrical law—that known as the law of rational indices, and the early part of the book is consequently devoted to the investigation of such a complex, and shows, further, how it is denoted and represented; this involves a series of propositions relating to axes and indices, to stereographic projection, and to the relations of zones. The idea of symmetry superimposed on such a geometrical complex is considered in the two following chapters, and the six systems, having thus been established, are considered in detail in chapter vii.

Although this treatise will certainly not prove attractive to readers who are totally unfamiliar with mathematical methods and conceptions, yet it succeeds in giving simple and elegant proofs (many of them new) of all the necessary theorems without introducing any advanced mathematics. At the same time the book is far from being a geometrical study. The eighth and ninth chapters, comprising more than one hundred pages, are devoted to the practical methods employed in the goniometrical measurement and calculation of angles, and to the manner in which crystals are depicted by projections and perspective drawings; further, each crystalline type is represented by copious examples from minerals and chemical products, and frequent references will be found to the bearing of certain physical investigations upon the points discussed. Such a complete treatment, for example, as is here given of the twinning of diamond, quartz, and felspar is infinitely more satisfactory than the meagre sketch usually found in text-books, whether of crystallography or mineralogy.

But the book contains far more than is indicated above: it is, at least so far as regards certain aspects of the subject, a really philosophic treatise, of which the originality and peculiar interest will be best appreciated by a reader who refers to the discussion of crystalloid symmetry contained in the fifth and sixth chapters. Here the nomenclature is to a large extent new, although some of the terms have become familiar in Mr. Gurney's little book, where they are mentioned as due to Prof. Maskelyne. Many of them are invaluable aids to precision: haplo- and diplo-hedral, meta- and anti-strophic, holo- and hemi-systematic, for example, are terms which avoid much circumlocution, introduce clear conceptions, and once used can scarcely be dispensed with.

The chapters dealing with symmetry must have been familiar to Prof. Maskelyne's pupils many years ago, at a time when the importance of this subject was by no means recognised; to him is undoubtedly due the credit of first in this country directing to crystal symmetry the consideration which it deserves, which, moreover, it failed to receive in the methods of Miller. In the present book symmetry is of cardinal importance; the systems are deduced from a discussion of the possible forms which may be assumed by the systematic triangle, *i.e.* the triangle formed by the intersection of a sphere with three adjacent planes of symmetry; the mero-symmetrical divisions of the systems are then considered as resulting from the possible "presence or absence of certain faces consequent upon the abeyance of the actual symmetrical character of planes which are otherwise potentially planes of symmetry"; in other words, the symmetry of the system is regarded as a complete type latent in the hemihedral and tetartohedral crystals, and exercising a symmetrical influence by virtue of the axes of symmetry, which are themselves the result of dormant planes of symmetry.

Now in recent years new methods of treating crystallography, also mainly from the point of view of symmetry, have been developed in other countries; to avoid criticising the present treatise in the light of the newer teaching, would be to shirk a responsibility obviously imposed upon a conscientious review.

One method frames a theory of crystal structure which shall accord with the observed homogeneity of crystals, finds in how many ways such structures may be symmetrical, and so deduces the systems; such is the course pursued in Mallard's magnificent treatise upon the basis of Bravais' theory of structure, and a similar method

might be based upon a more extended theory, such as that of Sohncke or that of Fedorow and Schonflies, and would lead to all known varieties of crystal symmetry. Such a deductive method is not, however, one which has ever commended itself to scientific teachers in this country, and it is not one which can be logically adopted in a book dealing solely with the morphology of crystals.

The second method is the one introduced by Gadolin; it inquires in how many ways a figure obeying the law of rational indices can be symmetrical according to the number and distribution of its planes and axes of symmetry, and it leads satisfactorily to all the known varieties of crystals. It was employed by Liebisch, and has been carried to its utmost extreme in the new edition of Groth's "Physikalische Krystallographie," where the systems are geometrically little more than artificial groups constructed by synthesis of the various types, the conception of mero-symmetry being completely abandoned. Prof. Maskelyne treats of planes before axes of symmetry, and regards the latter as begotten by the former; accordingly he is compelled to introduce the idea of mero-symmetry as a second empirical law, whereas the method of Gadolin requires the one law of rational indices alone. In the opinion of the present writer, Gadolin's is the most, indeed the only, logical process. It must, however, be confessed that the method of Prof. Maskelyne possesses a simplicity which is important from the educational point of view, and might alone be sufficient justification for its use; that he has considered and rejected other possible courses is clear from the discussion on p. 171, which leads to the following suggestive remark: "It is, however, evident that the whole treatment of crystallographic symmetry on the assumption of planes and axes of symmetry, actual or potential, represents a geometrical abstraction; an abstraction that needs for its development and due explanation a complete science of position applied to the molecular mass-centres."

In the preface it is stated that the greater part of the present treatise has long been in print; this being the case, the earlier part must inevitably be somewhat out of touch with recent discovery, and since there is no list of errata, statements which are not, like the geometrical propositions, unassailable, must be received with due caution. Thus milk-sugar is stated to be orthorhombic, it has recently been proved mono-symmetric; the whole of § 314 should now be cancelled. Again, § 140 must be read in the light of § 266. Cuprite is described both as holo-symmetrical and as hemi-symmetrical; but the intelligent reader will find the most important of such contradictions implicitly corrected in a table of crystalline types, with authentic examples, given on p. 502. This table is introductory to eight useful plates which deserve special attention, since they represent all the varieties of merohedra and their relations, and render the previous descriptions easily intelligible.

The appearance of this book is an interesting event in the history of crystallography. The volume stands as a striking and permanent record of the original manner in which this science has for many years been treated by the Oxford Professor in lectures, of which the substance is now for the first time made public. By those who have had the privilege of personal acquaintance with his teaching, it will be welcomed as the familiar echo of a style of exposition singularly adapted to kindle enthusiasm for an abstruse subject, and by the scientific public, as an authoritative treatise on a science of which the growing importance is continually becoming more fully recognised.

H. A. MIERS.

THE STUDY OF STEREOCHEMISTRY.

Stéréochimie. Exposé des théories de Le Bel et Van't Hoff. Par E. G. Monod, avec une préface de M. C. Friedel. (Paris: Gauthier-Villars et Fils, 1895.)

THIS is a small book of 162 pages which gives a clear account of the fundamental ideas upon which is founded the modern doctrine of chemistry in space, which sprang, as every one knows, out of Pasteur's classical researches on the relation between optical activity and crystalline form. Much fault need not be found with this book because it contains rather dogmatic statements of debatable propositions, but we venture to think the treatment of the subject too sketchy and superficial to afford much real help to the student.

M. Monod's little book relates only to the stereochemistry of carbon, and the isomerism of nitrogen compounds is not referred to. Now this department of theoretical chemistry is one which should be entered by the student at a comparatively advanced stage of his progress, when he is already familiar with the more important facts upon which the theory is based. It seems doubtful, therefore, whether so scanty an outline as this will supply what is wanted by students at this stage. They will desire to be told not only that a certain number of groupings are possible with a stated number of carbon atoms, which is usually obvious enough, but they will require to be told something of the secondary hypotheses with which the fundamental idea has become encrusted. For example, the union between two carbon atoms joined by a single bond is shown (p. 17) to be "mobile," that is, each carbon is supposed to be able to rotate, together with its attached radicles, round the axis joining the two carbons; but the student is left at that point to wonder why it should rotate at all. It is only much later (p. 63), in connection with the isomerism of fumaric and maleic acids, that reference is made to the doctrine of attractions between the radicles associated with carbon atoms adjacent to each other. In this case it is not justifiable to say that the attraction of CO_2H for H is *evidently* greater than that of CO_2H for CO_2H or H for H. There is nothing *evident* about the statement, which is almost purely hypothetical, such evidence as does exist tending almost as much one way as the other.

Throughout the book the conventional tetrahedron is the symbol used, and we have not been able to find any account of Wunderlich's hypothesis as to the configuration and union of carbon atoms, nor of Baeyer's strain theory in the formation of closed chains, nor of any other explanation of the way in which two carbons may unite by double or triple bonds, and the consequences of such union.

The most interesting part of the book is the brief fourth section, which relates to the researches and hypotheses of Guye as to the relation between the rotatory power of the substance and the masses of the radicles attached to an asymmetric carbon in the molecule of an optically active compound.

One word more. The short preface by Prof. Friedel explains, as follows, the object of the book: "La branche de la science chimique à laquelle on a donné le nom de stéréochimie ou chimie dans l'espace est de date toute récente. Elle a été créé par MM. A. Le Bel et Van't Hoff: . . . A l'étranger les publications d'ensemble faites pour répandre ces notions ne manquent pas. Il n'en est pas de même en France," &c. This seems strange, while close by, rue S. André des Arts, may be had Meyerhoffer's edition of Van't Hoff's celebrated "Dix années dans l'histoire d'une théorie," a book of infinitely greater interest than the volume before us.

A practice has grown up of late years of inserting into text-books by obscure authors little prefaces by better-known men, containing nothing in particular in the way of information, and in which the laudatory expressions are not always quite justified by the character of the book. So long as "puffing" is regarded as allowable, there is no very clear reason why it should not be permitted in connection with books; but the sort of preface referred to, has rather too strong a family likeness to the "certificate" so often found on the label of hair-restorers and packets of cocoa, to the virtues of which these writers of prefaces would probably in most cases shrink from testifying.

OUR BOOK SHELF.

The Telephone Systems of the Continent of Europe. By A. R. Bennett. (London: Longmans, 1895.)

With what object was this book written? The introduction is a violent diatribe against the telephone powers that be in England; and yet by his titles, the author seems to have been nursed in their service. Moreover, England and Germany with their 162,000 telephones, rank next to the United States, and possess more telephones than all the rest of Europe put together. In fact, next to Scandinavia and Switzerland, England ranks above Germany in telephonic development—the rest of Europe being "nowhere." Why, therefore, this wailing and gnashing of teeth? Why should England and Germany alone in Europe excite his wrath? Is it that they will not adopt at home his views of low rates and, perhaps, no profits, and did his apparent rough treatment in Berlin prejudice his judgment of German ways? The book is full of statistics of the growth and development of the business in different European countries—except England. It indicates the public uses to which telephones can be applied, but it contains little that is scientific or practical. Its facts are fleeting, and its *raison d'être* is not evident.

The development of telephony in Sweden is very remarkable. The difficulty of locomotion, and the long dark days in winter, may account for much of it. In a population of 4,824,000 there are 26,201 telephones in use. This means one telephone to 184 inhabitants. In the United States there is one telephone to 270 inhabitants.

In Switzerland it is even more developed than in Sweden. The difficulties of locomotion and internal communication, the isolation of valleys, that gold mine to the country—the great summer tourist traffic—and hotel life, may account for this, but the author attributes its success solely to its cheapness. In fact it is too cheap, for it does not pay, and this state of things is not conducive to future prosperity.

The great development of telephony in the United States, where there are 232,140 subscribers in spite of very high rates, does not support the views of the author.

The annual charge in Switzerland was originally 150 francs per annum for an unlimited local service, and an additional 25 francs per annum to cover trunk or inter-urban service. It was soon found necessary to charge 20 centimes per talk of five minutes on trunk lines. Since 1890 the local charges have been 80 francs per annum with 800 free talks, and 5 centimes per extra talk, and the trunk charges per three minutes, 30 centimes for any distance up to 50 kil., 50c. to 100 kil., and above 100 kil. 75c. From January 1, 1896, it will be a very practical and sensible tariff, viz. an initial annual charge of 40 francs and a uniform charge of 5 centimes for all local talks, the trunk charges remaining unchanged. The number of talks per annnm per subscriber during 1894 was—local 504 and trunk 85, but the trunk traffic in many places far exceeds the local. In Affoltern, for instance, during 1894, there were only 105 local talks, while the trunk talks amounted to 8167 (*Journal Télégraphique*, May 25, 1895). There were at the end of 1894, 18,814 subscribers in Switzerland. This means one telephone to 147 inhabitants.

A word is wanted badly to express a telephonic conversation or talk analogous to "telegram." The author's "telephonogram" is lengthy. "Phonogram" is in use in connection with the phonograph. "Telelogue" has been proposed, but has not met with general approval

The Elements of Health. By Louis C. Parkes, M.D., D.P.H. (London: J. and A. Churchill, 1895.)

The author of this manual states in the preface that his "main idea has been to give some simple yet practical information on the preservation of individual or personal health." It is impossible to say, with any degree of certainty, who is to be accorded the distinction of having originated such an "idea." Certainly Hippocrates undertook the writing of treatises on hygiene, and even he was only following in the footsteps of others. This preliminary remark mainly arises out of the fact that when another manual of hygiene appears, one's natural impulse is to turn to the preface, in order to see if the author has any new motive to suggest for its appearance; for the fact is, there is, at present, a superabundance of such works. Dr. Parkes' manual, good as it is, contains practically nothing that cannot be found in any of the other dozen or more elementary treatises dealing with the same subject; and to those who are familiar with the same author's work upon "Hygiene and Public Health," it will be sufficient to state that the present volume under review is practically that work popularised and very much abridged.

The illustrations are excellent; and it is a positive relief to find that they show a little freshness in their treatment, and are something more than the stock figures that appear in so many similar publications.

Dr. Parkes occupies a deservedly high position among sanitarians, and it goes without saying that his teachings are sound. There are only two points which call for adverse criticism. The table on page 168 needs revision: the author is well aware that the fat in butter does not average 88 per cent.; indeed, on a subsequent page (196) he himself puts it down at 83 per cent.; and his statement that it is "doubtful if alum (in bread), unless present in considerable quantity, is able to influence health adversely," is also open to criticism. In the first place, it is doubtful whether, if such be the case, it is prudent to make so loose a statement in what is designed to be a popular work for the lay reader. There is little doubt that the hydrate of alumina, which results from the use of baking powders containing alum, is soluble in the hydrochloric acid of the gastric juice, and there are many good reasons for regarding such addition as very undesirable; it would, moreover, probably prove harmful when present in what may be held to constitute less than a *considerable quantity*.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Hypnotised Lizards.

SEVERAL communications relating to the so-called "death-feigning instinct" of certain reptiles have appeared in the columns of NATURE during the last few months. The following observations bearing on this question may be of sufficient interest to justify publication. They refer to a species of lizard of the genus Stellio (identified in Tristram's "Fauna and Flora of Palestine" as *S. cordylina*), which is extremely common in these parts. When one of these lizards is captured, it makes a few vigorous efforts to escape, and then, if held firmly, falls into a limp, motionless state, which might easily lead an inexperienced person to think it dead. A very little examination, however, shows that the animal is not dead, but in a trance-like condition. Gentle respiratory movements are visible just behind the shoulders, and sometimes show a rising and falling rhythm with short intervals of complete rest; the eyes may remain wide open, but are commonly half-closed, and the lids wink slowly from time to time spontaneously or by reflex action; the mouth is almost always open—sometimes wide, sometimes but little—and in either case the jaw is quite rigid, and if closed by force is apt to reopen when the pressure is withdrawn; the limbs lie extended and semi-flaccid, with some approach to a cataleptic condition, *i.e.* if bent, or stretched into positions not too strained, they maintain such positions when let go; and the same is true of the trunk and tail. If, now, the lizard be laid down gently on the floor or on a table, it will lie perfectly still and seemingly unconscious for some minutes (unless roused by a sudden jar or loud noise), the eyes preserving throughout a peculiarly vacant, expressionless aspect, quite suggestive of death. While in this state the lizard may be put into a variety of positions without eliciting any sign of consciousness, and will lie as quietly on its back as in the natural position; and I have without difficulty made one maintain various grotesque postures, such as standing erect with one hand resting on the edge of a book, like a preacher behind a pulpit; bending sharply around, and seizing the tail with the claws of one fore-foot; cocking the tail over the back, scorpion fashion, &c.

Although some reflex actions are maintained (*e.g.* winking, as above mentioned), there is a considerable degree of cutaneous anæsthesia, as shown by the fact that a pin may be run through a fold of skin without fully rousing the animal, a sluggish, feeble wriggle being the sole result.

This trance state (obviously akin to some phases of hypnotism) lasts, as before stated, for several minutes. I have on several occasions timed it, the lizard being laid on its back, and myself concealed or standing quite still at a distance, and in each instance recovery seemed to come suddenly after about five minutes (sometimes a few seconds less, sometimes more), the animal showing no sign of consciousness until by one brusque effort it turned over into the normal position; this done, it lies quite still, but evidently awake and observant, for a few moments more, and then scuttles off in a hurry.

I find that the readiest way of inducing the trance is to take the lizard's head between my finger and thumb, making gentle pressure upon the angles of the jaw and upon the tympanic membranes; but similar pressure on the sides of the trunk, just behind the fore limbs, is just about as effective.

Such are the facts: and it seems to me that, so far as the animal in question is concerned, they lend no support whatever to the hypothesis of voluntary or conscious death-feigning; but, on the contrary, are perfectly consistent with the view that such phenomena belong to the same class as the various manifestations of hypnotism, &c., with which we are all more or less familiar in the human subject.

Supposing, however, for the sake of argument, that we have to do here with a true instinct, and not, as I believe, with a mere neurosis—an incidental reaction of the higher nervous centres—what possible purpose could such an instinct serve? The natural enemies of these lizards are foxes, jackals, martens, birds of prey, and snakes. Can any one believe that any one of these animals, having captured a lizard, would be in the least inclined to let it go because it lay motionless and apparently dead in the captor's grasp? Or will it be argued that the trance condition is a special gift "in mercy" to the victim, to mitigate or abolish the pain of death? If the last be the true explanation, one is tempted to ask why such tenderness is shown to a favoured few of the victims in nature's wondrous system, while the majority (*pace* Dr. A. R. Wallace) are left in possession of consciousness and sensibility more or less acute until they have sustained enough mechanical injury to kill or stun them.

Beyrout, Syria, May 16.

Stridulating Organ in a Spider.

IT is exactly twenty years now since I described to Geoffry Nevill the sound made by our large "Bhaluk Mokra" (or Bear Spider). I noticed that Wood Mason, who sat opposite me, appeared to be highly amused, but he said nothing.

Next morning when he joined Nevill and me at table, Mason was in high glee, and said, "I've found out all about your wonderful spider. I thought yesterday you were telling Nevill a stiff yarn for amusement, but as it wasn't your usual custom, I unbottled a lot of the big spiders, and found the stridulating apparatus."

He there and then made me recite all over again, and promise to write out, what he quoted in the *Trans. Ent. Soc.*, 1877, and give him a sketch, which is plate vii.: a previous notice of it all appearing in our *Proc. As. Soc.*, Bengal, 1876, and *Ann. and Mag. Nat. Hist.*

It was in the cold season of 1869–70 that I captured the specimen, and noticed the stridulating phenomena. The sound can be heard easily at ten or twelve yards, and is like pouring small shot on a plate.

I should not have mentioned the above, were it not that my report of "sound-producing Ants" seems to have been overlooked. If I mistake not, Sir John Lubbock looks on them as a silent group; but it is ten or twelve years now since I drew attention to the sounds made, and gave a small "Morse" diagram of the same, either in NATURE or the *English Mechanic*, one kind of ant giving a series of triple sounds, another kind a set of five or six, gradually decreasing.

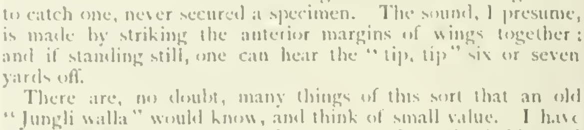
I described how the sounds were made by rasping the horny tip of the last abdominal segment on any resonant material, such as thin dry bark, dry leaves, &c.

I am not aware if the tolerably loud percussive "tok-tok" of the Mahsir (*BarbessMacrocep*) is known. I described it to a friend in England in 1879, and saw it quoted in the *Daily Telegraph* (about August to October) soon after.

While on this subject, I may mention that we have a rather rare butterfly here, which is dark in colour, some three inches across, a very hard flyer, and when darting about (generally after sunset), in a shady avenue, makes a series of taps, sounding like "tip, tip, tip."

Three or four of these butterflies generally fly together. I have not seen one alone; and though I have often enough tried to catch one, never secured a specimen. The sound, I presume, is made by striking the anterior margins of wings together; and if standing still, one can hear the "tip, tip" six or seven yards off.

There are, no doubt, many things of this sort that an old "Jungli walla" would know, and think of small value. I have been surprised at the little often known about the habits and appearance of many animals and insects. Not three years ago,



a well-known naturalist was quite interested in my description of the "happy family" one often finds in the holes, a little above water level, in our clay banks of small rivers, at low water during cold season; fish of several kinds, and crabs (three and four inches across) living together in the hole under water as a "colony." But for these tolerably deep holes, the otters would leave no fish in the smaller rivers.

The Migrations of the Lemmings.

Although I have dwelt among the Lemmings for many years, and paid great attention to their migrations, I have thought it might be more satisfactory to my readers to record the result of an interview with a captive member of the tribe, as recorded by the aid of a phonograph, assisted by a certain legitimate amount of amplification which the poverty of the language necessitates. This, however, I am convinced is what my little prisoner intended to say. "I am amused by the reasons men give for our sudden appearances and inexplicable migrations. But, although I do not see why I should enlighten you on either of these points, especially as you would probably only stick the harder to your own opinion, I will venture to ask whether you think we cross wide lakes, the opposite shores of which are quite invisible to us, in order to find the food which we thus abandon; indeed, though I fear I am somewhat letting what you call the cat out of the bag by saying it, I have often wondered why I myself did not wander along the green shores of Heimdalsvand and down the valley amid sweet grasses and clover, instead of swimming across to barren Valders, and getting caught by you for my pains. But, after all, it is no worse than when my friends the swallows leave their flies, and even their families, and start on their travels, when the impulse seizes them, whilst the former are still plentiful, and the latter not yet ungrateful. So I feel indignant at the suggestion that we travel because we are overcrowded and underfed at home. I admit that our temper as a race is somewhat short; it has been impaired by incessant bullying. Dogs, wolves, and lynxes eat us wholesale; and the reindeer disgustingly declare that we are a mere bag of succulent *saur-kraut*. Shadows annoy us, and you men have even invoked spiritual weapons to aid your carnal implements of destruction. But let me seriously advise you not to fling about inappropriate epithets; our customs are at least as good as your own, and probably somewhat older, for we too have had an ancestry, and *noblesse oblige*. Enough; let me out; I want to get on." W. Duppa-Crotch.

Richmond, Surrey.

Boltzmann's Minimum Theorem.

There is a point of great interest, in connection with Mr. Burbury's letter in your issue of May 30, on which he has not touched.

The expression obtained in the Boltzmann theorem for the value of $\frac{dH}{dt}$ depends on the assumption that the actual distribution is at every instant absolutely identical with the most probable distribution. This we know cannot be exactly true. Therefore the value of $\frac{dH}{dt}$ in Boltzmann's theorem is not identified with the *most probable* value of $\frac{dH}{dt}$. It is, for instance, quite possible, in the absence of proof to the contrary, that no matter in what way the actual distribution differs from the most probable one, the actual $\frac{dH}{dt}$ may be numerically smaller than the value corresponding to the most probable distribution.

In that case Boltzmann's theorem would give the maximum rate of subsidence instead of the most probable rate. Can Mr. Burbury or Dr. Boltzmann throw any light on this question?

Edwd. P. Culverwell.

Trinity College, Dublin, June 1.

THE CAMBRIDGE NATURAL HISTORY.[1]

Although the third in the series, this volume is the first of the long-promised "Cambridge Natural History" to appear, and as such excites additional interest because it affords some clue to the probable style of the remainder—probable, since "complete uniformity of treatment has not," we are told, "been aimed at. It is worthy of remark that, contrary to what obtains in most popular works on natural history, the Invertebrates are to receive their fair share of attention, and to extend over nearly seven of the ten volumes projected. It is almost a Cambridge work in a double sense, for with the exception of Prof. Herdman, who is to write on the "Ascidians and *Amphioxus*," and Mr. F. E. Beddard, who will undertake two such widely separated subjects as "Earthworms and Leeches" and "Mammals," all the contributors are connected with that University.

"'The Cambridge Natural History' is intended," the publishers announce, "in the first instance for those who have not had any special scientific training, and who are not necessarily acquainted with scientific language. At the same time an attempt is made not only to combine popular treatment with the latest results of modern scientific research, but to make the volumes useful to those who may be regarded as serious students in the various subjects. Certain parts have the character of a work of reference."

By this standard, then, the present volume must be judged; and on opening its leaves and turning over its pages, with their abundance of new and beautiful illustrations, it is at once manifest that artist and engraver, printer and publisher, have vied with each other to produce a work worthy of the conception.

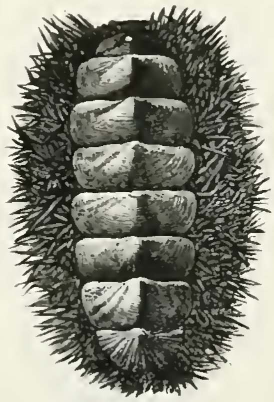

Fig. 1.—*Chiton Spinosus*, Brug.

The major portion, or, to be precise, 459 pages of the whole, is devoted to the Mollusca. It is no fault of the author's if it has to be admitted that a treatise on this branch of natural history, at once popular and scientific, still remains to be written. Mr. Cooke, who is responsible for this section, save for a casual passage or phrase here and there, has produced a most readable work: but the burden laid on his shoulders is greater than one man can bear nowadays, for no single individual can be a specialist in all the numerous branches of the subject; and yet nothing short of special knowledge in every ramification is adequate for the production of a text-book. The co-operation of specialists is yearly becoming more and more of a necessity in compiling manuals if good work is to be achieved, and in our opinion the system of minute subdivision, adopted for example in the "Standard Natural History," which was published some years ago in America, is the only wise one.

It is not, therefore, any matter for wonder that Mr. Cooke has had to resort largely to compilation, with the inevitable result that facts here presented in one form of phraseology, would, with a more intimate personal knowledge, have been differently expressed. Thus, for example, when speaking of barriers to distribution, we are told that "ranges of inferior altitude, such as the Pyrenees, the Carpathians, and the Alleghanies, may be turned in flank as well as scaled," and when he wrote, "The Mediterranean offers no effectual barrier" the author evidently did not take into consideration the altered distribution of sea and land in the Mediterranean region during Pleistocene

[1] "The Cambridge Natural History." Edited by S. F. Harmer, M.A., and A. E. Shipley, M.A. Vol. iii. "Molluscs." By the Rev. A. H. Cooke, M.A. "Brachiopods" (Recent). By A. E. Shipley, M.A. "Brachiopods" (Fossil). By F. R. C. Reed, M.A. Pp. xii. 535; 334 Figures in text, and 3 Maps. 8vo. (London: Macmillan and Co., 1895.)

times. Whilst in this respect the work, for a text-book, suffers unavoidably from too much of the "study," it, on the other hand, would have been better if an extension of time had been allowed the author in which to weld his mass of interesting and valuable material into a more homogeneous whole.

The method of treatment of the subject, differing as it does in many respects from that of the ordinary handbook, will best be gathered from a brief recapitulation of the order in which the main points are taken.

Prefixed is a scheme of the classification adopted; and concerning this it will be more convenient to speak later on. The opening pages are devoted to a brief introductory statement defining the relationship of the Mollusca to the rest of the animal kingdom, and sketching their classification so far as the principal groups are concerned. Only one phylogenetic table is submitted, and that, unfortunately, the misleading one dividing the Mollusca into the utterly unnatural groups of Glossophora and Aglossa. On the other hand, Mr. Cooke is cordially to be congratulated on refusing to have aught to do with that mythical monster, the "archi-" or "schematic-mollusc." A discussion on the origin of the land and fresh-water mollusca follows, and leads up to chapter ii., which deals with the habits and economy of the non-marine forms. Enemies of the mollusca, means of defence, parasitic mollusca, commensalism, and variation occupy the next chapter. Field malacologists especially will appreciate the bionomical facts and fancies here carefully gathered together from innumerable minor sources, and presented in available form; indeed, were it not from lack of space, we would gladly quote largely out of this, the most interesting portion of the work from a popular point of view. In the succeeding four chapters (v.–viii.), the anatomy, or rather the comparative anatomy, and embryology of the several classes are dealt with. The shell and the designation of its parts come next. Distribution (in space) forms the theme of the three subsequent chapters, and here the non-marine have preference by two to one over the marine mollusca. Three maps accompany and "illustrate" this section, by obviating the necessity of referring to an atlas. Finally, there is the systematic portion, in which a brief description is given of the principal characters of each family with its distribution in time, and a list of the more important genera composing it.

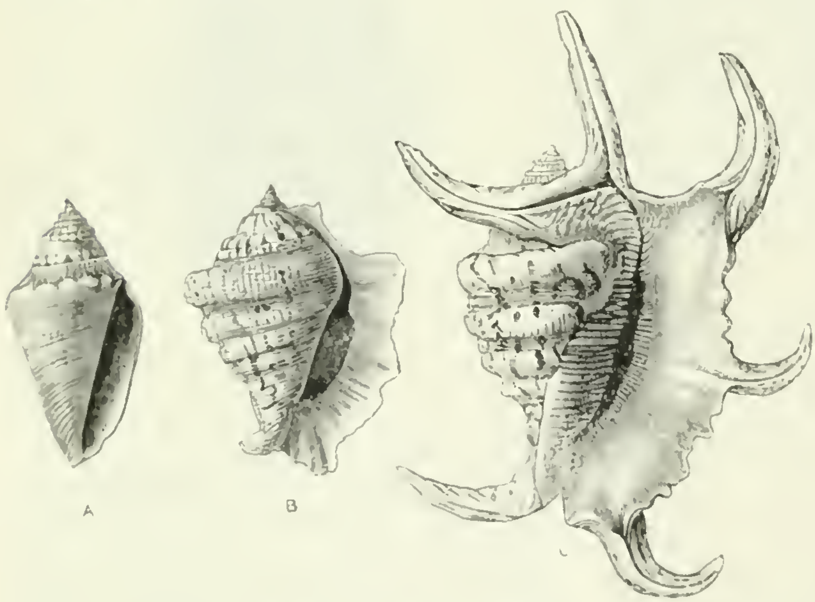

Fig. — Three stages in the growth of *Pteroceras rugosa*, Sow.

In great part, therefore, the present work reverses the method adopted in most modern text-books, wherein it is customary to describe the animals first and discuss their habits afterwards; the writer has, in fact, followed the arrangement adopted in the preliminary chapters of Woodward's "Manual," rather than that in Fischer's. This system of inversion also obtains in the anatomical portion; reproduction, usually reserved for the last, being put first apparently, with some idea of starting at the beginning of the molluscan career. The principle may undoubtedly possess advantages, but it also has its drawbacks. For example, the nomenclature of the parts, or topography, of the shell is not given till the close of chapter ix., whilst many of the terms there first defined have previously been freely employed, and that although the student is theoretically not expected to be acquainted with anything beforehand.

This is a detail which the editors should have attended to, for wherein their utility if not to assist by bringing a fresh and impartial eye to bear on the work they supervise, since however able a writer may be, he is naturally apt when engrossed with his task to overlook such minutiæ. So, too, they should have noted that the "classes" have in the opening pages, by a slip of the pen, been called "orders." They might also, though it is not fair to charge it to their account, have observed that whilst at p. 14 *Dreissensia* and *Mytilopsis* are spoken of as "scarcely modified *Mytili*," these two genera are in the systematic part correctly referred to a totally different order from *Mytilus*. The author himself, however, must be held responsible for having overlooked Dr. Carpenter's retraction of his theory of shell formation in the later editions of "The Microscope," and for such other oversights as referring the well-known and beautiful *Choanopoma hystrix*, from Cuba, to the genus *Cylindrella*, or describing *Strombus* as "frugivorous."

Although on so vexed a question as classification the greatest latitude seems allowable, yet certain points in the one here adopted call for remark. For instance, the Amphineura are retained as an order of Gastropoda (Mr. Cooke prefers the older and, we think, less correct spelling of Gasteropoda) in contradistinction to the opinion of recent authorities such as Pelseneer, Simroth, &c. Moreover, by-the-by, why is Pilsbry's classification of the Chitons passed over for an older and less complete one? What to do with the Pteropoda, Mr. Cooke was apparently in doubt when he began his book (pp. 6, 7), but in the systematic part at the close, their affinities with the Tectibranchiate Opisthobranchs is duly pointed out. At the same time, though their two main divisions, Thecosomata and Gymnosomata, are most closely allied to the Bulloidea and the Aplysioidea respectively, the Pteropoda are here for convenience sake retained as a group by themselves of equal rank with the Tectibranchiata as a whole. This, if not exactly logical, is comprehensible, but not so the separation of these two sections by the interposition of the Ascoglossa and Nudibranchiata.

About the Heteropoda, on the other hand, our author has no scruples, and though they retained their independence to a later date than the Pteropoda, they are referred without comment, albeit correctly, to the Prosobranchiata, and even, following Lang, to the Tænioglossa.

The term Platypoda, founded to include all the Pectinibranchiate Prosobranchs except the Heteropoda, is here restricted and made to apply, without reason given, to the Tænioglossa other than the Heteropoda.

Those interesting and somewhat anomalous genera *Siphonaria* and *Gadinia*, Mr. Cooke, in accordance with the conclusions lately arrived at by Köhler, Haller and Plate, places with the Tectibranchiata, creating for them the sectional name of Siphonarioidea. Pelseneer, we may incidentally remark, in his "Recherches sur divers Opisthobranches," which has only just been published, objects to this conclusion of his German *confrères*, and seemingly on very good grounds.

The Brachiopoda, which are incorporated at the end of the volume, are subdivided into "recent" and "fossil." The former (pp. 463-88) have been undertaken by one of the editors, Mr. A. E. Shipley; the latter (pp. 491-512), by Mr. F. R. Cowper Reed.

Mr. Shipley's chapter is a compact little summary, pithily written, and whilst not erring on the side of popularity, ought to be readily followed by any average student or reader.

It consists almost entirely of anatomical description, embryology, &c., for in "habits" the Brachiopoda are extremely deficient, preceded by a short sketch of the historical bibliography of the group, and followed by a few notes on their distribution, with a synopsis of their classification by Davidson.

Mr. Shipley concludes that the affinities of the Brachiopoda "seem to be perhaps more closely with the

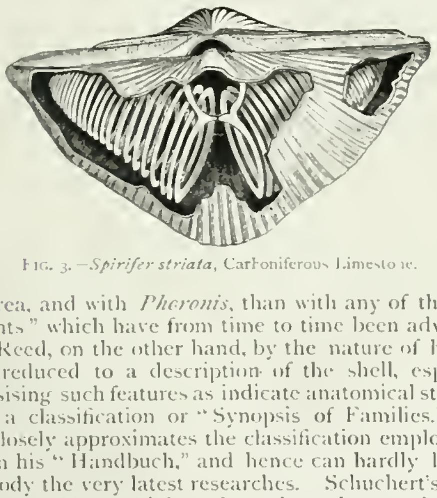

FIG. 3.—*Spirifer striata*, Carboniferous Limestone.

Gephyrea, and with *Phoronis*, than with any of the other claimants" which have from time to time been advanced.

Mr. Reed, on the other hand, by the nature of his subject, is reduced to a description of the shell, especially emphasising such features as indicate anatomical structure and to a classification or "Synopsis of Families." The latter closely approximates the classification employed by Zittel in his "Handbuch," and hence can hardly be said to embody the very latest researches. Schuchert's classification should, we think, at least, have been referred to. Some allusion, too, ought to have been made to *Trematobolus*, which its discoverer, Mr. G. F. Matthew, describes as possessing articulate valves, though it is allied to the Obolidæ. Mr. Reed's descriptive writing must be accorded equal praise with that of Mr. Shipley for clearness of style.

Through the kindness of the editors and the publishers, we are enabled to reproduce some of the illustrations in the text. These of themselves should serve to distinguish "The Cambridge Natural History" from most of its competitors for popular favour, with their plentiful reproduction of ancient blocks, now, alas, too familiar to the eye, and by no means always joys for ever.

NOTES.

THE Ladies' soirée of the Royal Society took place yesterday evening, at the time NATURE went to press.

AN unknown donor has given to the University of the City of New York, funds for a central building, on University Heights, for a library, museum, and hall, so arranged that all may be turned into a library capable of holding 1,000,000 volumes. The gift will amount to 250,000 dollars, being the largest ever received in the sixty-six years of the existence of the University. The only condition is that the name of the donor shall never be revealed.

ARRANGEMENTS are being made by the Marine Biological Association for a series of dredging and trawling expeditions during July, August, and September, to investigate the fauna and flora of the outlying grounds between the Eddystone Rocks and Start Point. In order to make the results as complete as possible it is extremely desirable that the investigation of each group should be carried out by a competent naturalist. Zoologists and botanists who are willing to take part in these expeditions, or to assist in working out the material collected, are requested to communicate with the Director, the Laboratory, Plymouth.

THE summer meeting of the Institution of Naval Architects was opened at Paris on Tuesday, when Lord Brassey delivered his presidential address, and several papers were read and discussed. In the afternoon the members of the Institution visited the Paris Observatory and the Arts et Metiers, and a banquet was given at the Hotel Continental in the evening. After the close of the meeting, we shall give a report of the proceedings.

THE annual meeting of the Société des Amis des Sciences was held at Paris last week. The Society was founded by Thénard in 1857, for the purpose of affording assistance to men of science or their families. It numbers more than two thousand members or subscribers, and since its foundation has distributed nearly £50,000 to deserving investigators. Grants are only made to persons who have had papers or memoirs presented to the Academy of Sciences, or who have published papers of equal merit to those approved by the Academy. The Society lays stress on the fact that the grants must not be regarded as charitable doles, but as rewards for services to science, and of a similar nature to the pensions which a grateful country gives to its servants. The awards are therefore publicly announced, and are looked upon as honours for meritorious work.

THE Committee of the American Public Health Association, appointed to determine the possibility of establishing co-operative investigation into the bacteriology of water supplies, have made arrangements for a conference of bacteriologists to be held on June 21 and 22, in the Academy of Medicine, New York city. The conference will consider how to obtain increased exactitude in the details of bacteriological research, and establish standard methods. The conference will, in fact, attempt to establish some common ground-plan for systematic work in bacteriology in general, and in the bacteriology of water supplies in particular. The Bacteriological Departments of many State and Provincial and Municipal Boards of Health will be represented at the conference, as also the principal universities of the United States and Canada.

IN the eyes of the law, the Royal Agricultural Society is not a scientific institution which can claim exemption from local rates. It was decided in the Queen's Bench Division on Tuesday, that, as the funds of the Society are not exclusively applied to the purposes of science, but are used to promote "the comfort and welfare of labourers," the Society does not come within the statute under which exemption from rates is claimed.

COLONEL J. WATERHOUSE has been elected President of the Photographic Society of India for the current year.

THE summer meeting of the Geological Society of America will take place at Springfield, Massachusetts, on August 27 and 28.

We learn from *Science* that nearly a thousand dollars have been subscribed in the United States towards the memorial to Helmholtz.

This year's conversazione of the Institution of Electrical Engineers will be held in the Galleries of the Royal Institute of Painters in Water Colours, on Wednesday, July 3.

The third International Congress of Physiology will be held at Berne, from September 9 to September 13. An exhibition of physiological apparatus will be held at the same time. Those who desire to become members, or to read papers, should communicate with Prof. H. Kronecker, Berne, before August 1. The subscription is ten francs.

Several clearly marked earthquake disturbances have been felt at Florence during the past week. A strong shock, followed by two slighter shocks, was felt there at 1.30 a.m. on Thursday last. The shocks have done no damage in Florence, nor, so far as can be learned, in the surrounding country. The earthquake was most violent at Pontassieve, Rignano, and San Casciano.

Sir Samuel Wilson, whose death is announced, was greatly interested in science and education. Among other generous acts, he presented £30,000 to Melbourne University in 1875. He was Vice-President of the Melbourne International Exhibition of 1880, and a Royal Commissioner for the Fisheries Exhibition.

Among the recent appointments abroad we notice the following: Dr. Celakovsky to be Professor of Pharmacology in the Bohemian University at Prague; Dr. Rohde to be assistant in the Zoological Institute at Breslau; Dr. F. Trendelenburg, Professor of Surgery in Bonn University, to succeed the late Prof. Thiersch at Leipzig; Prof. J. v. Kries to be the late Prof. Ludwig's successor at Leipzig; Dr. F. Schütt, of Kiel, to Greifswald University as Professor of Botany, and Director of the Botanical Gardens and Museum; Dr. v. Knorre to the new chair of Electro-chemistry in the Technical High School at Charlottenburg; Prof. A. Overbeck, of Greifswald, to be Professor of Physics in the University of Tubingen; Dr. Hermann Struve to be Professor of Astronomy in Konigsberg University; Prof. E. Koken to be Professor of Geology and Mineralogy in Tubingen; Prof. R. Brauns to be Professor of Geology and Mineralogy in Giessen; Dr. T. Smith to be Professor of Applied Zoology in Harvard University.

In all parts of the British Islands, and especially over England, the weather has continued persistently dry: in the neighbourhood of London the total fall during the first eleven days of June did not exceed half a tenth inch, and the aggregate fall since the beginning of May, a period of six weeks, was but little over half an inch. The *Weekly Weather Report* of the 8th inst. showed that the amount of rainfall since the beginning of the year was below the average in all districts, except the north-east of England. In the west of Scotland the deficiency amounted to 10·4 inches. High summer temperatures have occurred during the past week in many parts of the country, the shade readings having reached 84° in the east of Scotland, and 83° in the south of England. In London, readings of 80° were recorded both on Saturday and Sunday last.

The Whitsuntide party at the Port Erin Biological Station included the following naturalists:—Mr. F. W. Gamble (Owens College), Mr. W. I. Beaumont (Cambridge), Dr. H. O. Forbes (Liverpool Museum), Mr. A. Leicester (Southport), and Prof. R. Boyce, Mr. A. Scott and Prof. Herdman, from Liverpool. Dredging, tow netting, shore collecting, and laboratory work were carried on much as usual. Amongst the more noteworthy animals obtained were *Polygordius* sp., *Sarcobotrylloides* sp., *Embletonia pulchra*, *Elysia viridis*, and *Cynthia morus*. The tow nets contained some fish eggs, but fewer than at Easter. Diatoms and gelatinous Algæ were nearly absent: Copepoda and larval forms were present in great abundance. Prof. R. Boyce and Prof. Herdman have commenced an investigation on the effect of surrounding conditions upon oysters, and their connection with disease. A number of oysters have been laid down in different parts of Port Erin bay and on the shore, and others are being experimentally treated with various fluids and food matters in the aquarium. Mr. W. I. Beaumont stays on for some weeks at the laboratory studying the Nemertines of the district, and the Rev. T. S. Lea goes to Port Erin shortly to assist Prof. Herdman in working out the detailed "zoning" of the shore and the distribution of the littoral animals.

The general arrangements for the sixth International Geographical Congress, to be opened in London towards the end of next month, are made known in a circular just distributed. The Congress promises to be truly international, for delegates have been appointed to represent Governments and Geographical Societies in all parts of the world. The provisional programme of the meetings is as follows:—The Congress will be opened on Friday, July 26, at 9 p.m., when short addresses of welcome will be delivered by H.R.H. the Duke of York, Honorary President, and by Mr. Clements R. Markham, President. On the following day, Mr. Markham will deliver his inaugural address, after which the Congress will meet in two sections to discuss papers on geographical education, by Profs. Levasseur and Lehmann, and others; and on mathematical geography, especially the use of photography in surveying, by Colonel Laussedat, Colonel Tanner, and others. On Monday, July 29, a general meeting of the Congress will discuss the subject of Arctic and Antarctic exploration, introduced by Prof. Neumayer and Admiral A. H. Markham. In the afternoon two sections will be formed, in one of which questions in geodesy will be treated by General Walker and M. Lallemand, while in the other papers will be read by Prince Roland Bonaparte on glaciers, and M. Martel on speleology. On July 30, report of Committees and papers on the proposed map of the world on the scale of 1 : 1,000,000, and on international geographical bibliography, will be presented at the general meeting, and two sections will then deal with oceanography, and with the orthography of place names. On Wednesday, July 31, Sir John Kirk will initiate a discussion on Europeans in Africa in the general meeting, and in the afternoon the sections will consider applied geography (commercial geography) and limnology, the latter to be introduced by Prof. Forel. The general meeting on August 1 will deal with the terminology of land forms, and in the afternoon cartography and other subjects will be treated. On Friday, August 2, the forenoon will be devoted to papers by Baron Nordenskiold, Prof. Hermann Wagner, and others, on the history of maps; and all the remaining papers will be taken in the afternoon. On August 3 the votes proposed for consideration will probably be discussed, the date and place of meeting of the next Congress considered, and the President will deliver his concluding address. After the close of the Congress, a series of excursions will be organised to places of geological and geographical interest.

The Rev. O. Fisher contributes a short paper on the age of the earth to the *Geological Magazine* for June. Arguing in favour of a comparatively thin crust and a liquid substratum, he urges that the continual laving of the bottom of the crust by the molten rock will retard the cooling of the crust, and will produce an effect on the temperature-gradient at the surface similar to that to which Prof. Perry has recently drawn attention (Nature, vol. li. pp. 224–227). If this be the case, then, no trustworthy estimate of the earth's age, based on the present temperature-gradient at the surface, has yet been made.

Dr. M. Cinelli has recently compiled a valuable list of the records of the Vicentini microseismograph at Siena between

July 15 and October 31, 1894 (*Atti. R. Acc. dei Fisiocritici*, v., 1895). An examination of the traces corresponding to seismic movements shows that they exhibit different kinds of oscillations, some short, others long, in period. When the earthquakes occur in neighbouring districts, the disturbance of the instrument is brief and the vibrations are rapid. But, with distant earthquakes, the disturbances last for much longer intervals. They begin with rapid oscillations which generally present several maxima, so as to appear as if distributed in groups; while towards the end, either alone or in company with the former, succeed much slower oscillations, which perhaps correspond to undulatory movements of the earth's crust.

DR. HOEBER has been making some interesting experiments to ascertain whether the presence of water-weeds affects the vitality of anthrax germs in water. For this purpose he constructed small fresh-water aquaria, each of which contained about eight litres of ordinary river Main water, some river sand, and a supply of water-weeds, and in addition about 200,000 anthrax microbes. These aquaria were only submitted to diffused light, and were kept at 10° and 19° C., respectively. Dr. Hoeber presumably worked with anthrax bacilli only, but special precautions were not taken to ensure the absence of spores; no anthrax germs, however, could be found after three days at the lower, and four days at the higher temperature, respectively. In his second report to the Royal Society, Prof. Percy Frankland states that *sporiferous* anthrax retained their vitality in ordinary river Thames water for upwards of seven months without losing their virulence; but when exposed to sunshine they were destroyed after eighty-four hours. On the other hand, when using *anthrax bacilli free from spores*, as derived from the dead body of an animal, the same authority (*Proceedings* Royal Society, 1894, p. 549) states that in sterilised river Thames and loch water they were destroyed in about five days at 5° C., and in fourteen days at 13° C.; but that at 19° C. they multiplied enormously, and were present in large numbers on the forty-second day. This different behaviour was found to be due to the bacilli having formed spores in the water at the higher temperature. The danger of anthrax germs gaining access to water depends, therefore, upon the temperature of the water and the presence or absence of spores in the morbific material. Judging by Dr. Hoeber's experiments, it would appear that the presence of water-weeds and the competition of water-bacteria may offer obstacles to the vitality of anthrax bacilli in water.

A SALE of much interest recently took place at the dispersal of the herd of white polled cattle belonging to Mr. R. E. Lofft, of Troston Hall, Bury St. Edmunds. The herd, which comprised twenty cows and heifers and five bulls, represented the old "monks' cattle," descended from the oldest historic breed of cattle in the British Isles—the polled white, with black or red points on the ears, muzzle, rims of eyes, and hoofs. Under the wave of improvement which set in with the work of Bakewell, of Dishley, more than a century ago, the old hornless white breeds no longer enjoyed the pride of place, and Mr. Lofft's herd really embodied an attempt to restore this ancient breed to something like its former position. It is probable that these cattle were originally selected by the monks, who in their day were the leaders of agriculture. Being hornless, the animals would be more easily domesticated, and less adapted to purposes of sport, such as the chase and bull-baiting. After the dissolution of the monasteries, these cattle were dispersed over the country, and mostly became merged in the common local varieties. A few, however, were kept pure, and at the beginning of this century there were two herds in Suffolk, which quite escaped the notice of the late Rev. John Storer, the historian of the breed. It is satisfactory to know that some of Mr. Lofft's quaint cattle were purchased by Mr. Assheton-Smith, of Vaynol Park, Carnarvonshire, where he has a herd of black-eared and black-muzzled white horned cattle, and is now going to keep some of the polled type.

PROF. L. DE MARCHI, the author of an Italian Hand-book of Meteorology, has contributed an important essay on the theory of cyclones to the *Pubblicazioni* of the Milan Observatory. The discussion consists of 42 small folio pages and 15 plates, and while giving a general account of recent researches, treats the subject chiefly from a mathematical point of view. The following is a brief summary of the principal results arrived at: The changes in the shape and path of a cyclone, as well as all the principal dynamic phenomena that accompany it, may be deduced from the equations of the horizontal motion, if account is taken of the distribution of temperature round the cyclone, both as regards that which previously existed in the mass of air subsequently occupied by the cyclone, and that drawn into the same area by the vertical movements produced by the earth's rotation. Therefore in some cases, if not always, it is useless to have recourse to external causes, and particularly to the general circulation of the atmosphere, to explain the persistence, change of form, or the motion of a cyclone. The general circulation may be the determining cause of a cyclone at a given point; its propagation, or the successive transference of cyclonic conditions to contiguous masses of air, is determined and maintained, at least in some cases, by the disturbances of thermic equilibrium caused by the sun at the surface of the earth, and induced by the earth's rotation.

THE old and fascinating problem concerning the manner in which the ether moves with or through matter has been attacked by Herr L. Zehnder, who contributes an interesting paper on the subject to *Wiedemann's Annalen*. He endeavoured to decide whether the ether is pushed along by atoms or bodies, or whether it passes through them without resistance, or, finally, whether only a portion of the ether adheres to the particles of bodies, and this portion only is carried along. The apparatus used consisted of a cast-iron cylinder in which a piston moved air-tight. A narrow tube led out from one end of the cylinder, doubled back upon itself, and returned by the other end. Now if the cylinder was exhausted of air, and the piston pushed the ether before it, the latter would stream through the narrow tube with a velocity greater than that of the piston in the ratio of the sectional areas of the cylinder and the tube. This ratio was 560, and exhaustion was carried to 1-40,000th of an atmosphere. To test the motion of the ether, a beam from a brilliant sodium flame was passed through two thick parallel glass plates, the second one being silvered at the back. This plate, by its two reflecting surfaces, split the beam into two, each of which travelled through one portion of the narrow tube. The two beams, reflected near the cylinder by a rectangular prism, were recombined by the same thick plate and returned along the way they had travelled, being finally reflected into the reading telescope by the first plate. Interference fringes were thus produced in the field of view, the motion of which would have indicated a motion of the ether. But no such motion was observed when the tubes were thoroughly exhausted, so that it must be concluded that the ether passes freely through solid bodies. The corollary to this conclusion, that there is a relative motion between the earth and the luminiferous ether, though investigated by the author by means of a new and ingenious apparatus on the Rosskopf, near Freiburg, could not be proved.

THE thirteenth part of Kerner and Oliver's "Natural History of Plants," just published by Messrs. Blackie and Son, refers chiefly to the production and characteristics of plant hybrids.

THE June *Journal* of the Chemical Society contains, in addition to papers read before the Society, and abstracts of other papers,

a description of the life-work of the late Prof. J. C. G. de Marignac, by Prof. P. T. Clève, together with a portrait of that lamented chemist.

Mr. C. L. Prince has sent us details of observations made made by him at Crowborough Hill, Sussex, during the great frost of January and February last. In his report, he contrasts the period with other periods of severe cold which have occurred during the present century.

The Guide-books to Middlesex and Hertfordshire, published by Messrs. Iliffe and Son, will direct the tourist's steps aright, and afford him instruction upon points of more or less historical interest, but they furnish very little information with regard to the counties from a scientific point of view.

We have received a "Guide to the Bristol Museum," by Mr. Edward Wilson, the Curator. The Museum contains a large number of valuable objects, and geology is very well represented. With this guide to assist them, students of science must find the collections more helpful than they used to be.

The Lumleian Lectures on certain points in the ætiology of disease, delivered by Dr. P. H. Pye-Smith, F.R.S., before the Royal College of Physicians in 1892, and the Harveian Oration, delivered before the College in the following year, have been published in volume form by Messrs. J. and A. Churchill. The volume also contains a memoir of the life and works of Harvey.

The fact that the report of the Marlborough College Natural History Society for the year 1894 runs into one hundred and fifty pages, may be taken as an indication that the Society is in a satisfactory condition. The report contains summaries of lectures delivered during the year, a description of the College museum and the collections in it, notes and observations, and accounts of the work of sections: it is altogether a creditable production.

Publishers' catalogues are frequently of great assistance to librarians and bibliographers. A catalogue lately issued by W. Engelmann, of Leipzig, belongs to that class of useful publications. It contains descriptions of all the books, memoirs, and periodicals published by Engelmann from the foundation of the firm to February of this year. The books are arranged alphabetically according to the authors' names, and are also classified into subjects. There is, therefore, no difficulty in finding a volume of which the author or the title is known.

The annual report of the Zoological Society of Philadelphia shows that, but for grants made by the City Councils, the Gardens would have had to be closed, the receipts from admissions having been too low to meet expenses. We notice that, in addition to nearly three thousand free admission tickets to charitable institutions, donors, &c., the Society issued fifty thousand tickets to the Board of Education, for the admission of pupils of the elementary schools. The collection of animals now comprises 251 mammals, 416 birds, and 245 reptiles and amphibians, or a total of 912 specimens.

The new editions received during the past few days include the second part of Dr. Michael Foster's standard "Text book of Physiology" (Macmillan), dealing with the tissues of chemical action and their respective mechanisms, and with nutrition. The work, which is now in its sixth edition, has been brought into line with the present state of physiological knowledge. Messrs. J. and A. Churchill have published a sixth revised edition of "A Treatise on Practical Chemistry," by Prof. Frank Clowes; and Messrs. Smith, Elder, and Co. have published a fourth edition of Marshall and Hurst's "Junior Course of Practical Zoology."

There are only four papers in the June number of *Science Progress*, but each of them is an important contribution to scientific literature. Prof. Marshall Ward describes the growth of knowledge concerning the fixation of free nitrogen by plants. He briefly states the aspects of the question, and gives references to the most important papers upon it. A valuable paper on the ratio of the specific heats of gases is contributed by Mr. J. W. Capstick: it affords interesting reading in connection with the recent discussion in these columns of points arising from the kinetic theory of gases, and also with reference to the atomicity of argon. Mr. J. W. Rodger concludes his most useful statement of the progress made in physical chemistry during 1894. The papers are classified in such a manner that it is easy to find what was done in every branch of the subject. The fourth paper is by Mr. J. E. S. Moore, and has for its subject "The Protoplastid Body and the Metaplastid Cell."

The current *Journal* of the Anthropological Institute (No. 4) contains the presidential address delivered by Prof. A. Macalister, F.R.S., in January last. The Institute by no means possesses a membership in proportion to the importance of the subjects fostered by it. "When we consider," remarks Prof. Macalister, "the wide-reaching importance of the myriad of practical problems with which we as anthropologists are concerned, and the useful work which the Institute has done in the past, it is scarcely conceivable that our membership of 302 should be taken as representing the number of persons to whom these matters are interesting. And further, it is little short of a national disgrace that in the largest empire of the world, within whose bounds there are nearly as many separate peoples, and tribes and kindreds and tongues as in all the other nations put together, there is no Imperial department whose function should be to collect and classify the facts of the physical, psychical, and ethical histories of our fellow subjects."

Two years ago the American Philosophical Society, of which Benjamin Franklin was the first President, held a meeting, at Philadelphia, in commemoration of the 150th anniversary of its foundation. The meeting was attended by delegates representing learned societies and institutions in most parts of the world, and was completely successful. The volume containing full reports of the proceedings has only lately appeared, but the delay in its publication is probably due to the many addresses, memoirs, and plates contained in it: for the printing of the communications, and the preparation of nearly sixty plates, necessarily takes time when the work is so carefully done as it seems to be in the volume before us. Among the addresses is one by Dr. Roberts (the delegate of the Royal Astronomical Society), entitled "Illustrations of Progress made during Recent Years in Astronomical Science." This address is illustrated by thirteen plates representing some of Dr. Roberts' classical photographs. A richly illustrated paper on Tertiary Tipulidæ, by Dr. S. H. Scudder, has already been noticed in these columns (vol. 50, p. 111). Seven plates illustrate Dr. A. S. Packard's "Study of the Transformation and Anatomy of *Lagoa crispata*, a Bombycine Moth," and sixteen embellish a paper by Prof. A. Hyatt on "The Phylogeny of an Acquired Characteristic." Limits of space prevent us from referring to the many other papers. Suffice it to say that the volume is a worthy memorial of a remarkable meeting.

The *Zeitschrift für Anorganische Chemie* gives a very complete account of the synthesis of metallic ores by crystallisation from solution in the appropriate molten metal, by Friedrich Roessler. The work includes the production of crystalline sulphides and selenides of such metals as lead, bismuth, and silver, and of arsenides, antimonides, and bismuthides of platinum, palladium, and gold. The production of silver bismuth

sulphide will serve to illustrate the method followed. Twenty grams of bismuth were melted in a covered crucible, and two grams of silver sulphide were added. By solution of the slowly cooled product in nitric acid of specific gravity 1·1, there remained small dark crystals intermixed with silver-white crystals. The latter consisted of a bismuth-silver alloy, and, in time, dissolved in the acid. On drying, the remaining dark crystals were found to possess a steel-blue lustre. They formed pretty groups of octahedra (figure given in the paper) attached in rows. Analyses proved their composition to be well represented by the formula, $AgBiS_2$ or $Ag_2S + Bi_2S_3$.

IN the current number of the *Comptes rendus*, M. Cleve gives the results of a determination of the density of the new gas helium by M. Langlet. The gas, extracted from cleveite, was freed from hydrogen by passage over red-hot copper oxide, and from nitrogen by metallic magnesium. It contained no argon. The density was found to be notably less than the number given by Prof. Ramsay, being 0·139 (air = 1) or 2·02 (hydrogen = 1). The determination of the specific heat of the gas has been taken in hand by the same investigators; their results will be awaited with much interest.

THE additions to the Zoological Society's Gardens during the past week include two Rhesus Monkeys (*Macacus rhesus*, ♂ ♀), from India, presented, respectively, by Sir Henry W. Peek, and Mr. R. Edmeades; a Patas Monkey (*Cercopithecus ruber*, ♀), from West Africa, presented by Mr. C. H. Armitage; a Campbell's Monkey (*Cercopithecus campbelli*, ♂), from West Africa, presented by Miss L. Panther; a Herring Gull (*Larus argentatus*), British, presented by Mr. J. T. Gorvin; three Ocellated Skinks (*Sepsocellatus*), a —— Skink (*Chalcides sepoides*), a Defenceless Lizard (*Agama inermis*), two Diademed Snakes (*Zamenis diadema*), two —— Snakes (*Cœlopeltis moilensis*), four Egyptian Eryx (*Eryx jaculus*), two Cerastes Vipers (*Vipera cerastes*), two Egyptian Cobras (*Naia haje*), from Lower Egypt, presented by Dr. John Anderson, F.R.S.; a White-crowned Monkey (*Cercocebus æthiops*), a White-necked Stork (*Dissura episcopus*), from West Africa; two White Pelicans (*Pelecanus onocrotalus*), from North Africa; a Barraband's Parrakeet (*Polytelis barrabandi*), from New South Wales; three Hamadryads (*Ophiophagus elaps*), from India; fifty Tree Frogs (*Hyla*), from America, deposited; a Red Deer (*Cervus elaphus*), an Argus Pheasant (*Argus giganteus*), three Ruddy-headed Geese (*Bernicla rubidiceps*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET 1892 V. (BARNARD). The orbit of this comet, which had been discussed by Mr. J. G. Porter (*Astronomical Journal*, No. 310), has recently been made the subject of a further investigation by M. J. Coniel; but the elements, resting as they do on a very few observations, still remain uncertain to a considerable extent. The comet was discovered, photographically, on October 12, 1892, and regular observations do not extend beyond November 22, 1892, about six weeks only from the date of discovery; but an isolated observation made at Nice on December 8, not taken into the discussion by Mr. Porter, induced M. J. Coniel to reopen the inquiry, with the hope of making a better determination of the period. Mr. Porter's orbit represented this observation within the errors - 0·05s. and - 12″·9, in R.A. and Declination respectively; and considering the difficulty of the observation, such a discrepancy is not more than might be anticipated, and consequently does not suggest the possibility of decided improvement. The feature of the more recent discussion is to show that the observations can be equally well satisfied with elements in which the mean daily motion is altered by some 20″. This is not quite the twentieth part of the whole motion, therefore the period is uncertain to its twentieth part, or about 0·3 of a year.

M. Coniel judges that the uncertainty in the mean motion may extend to 25″ on either side of his result, and that the period may lie between 6·23 and 6·84 years. The consequence of this uncertainty is that the search for the comet at future returns must be greatly extended. In 1899, the sweeping ephemeris must be based on a mean motion corresponding to 6·65–6·84 years. In 1905, the comet may be visible if the period lies between 6·34–6·55 years; while in 1911, and even 1912, the return may be expected with still other and possible values of the mean motion. No near approach to Jupiter will take place during this interval, but the situation of the orbit is such that the comet can approach both Jupiter and Mars. Confining attention to the most probable period (6·52 years), the comet approaches the orbit of Jupiter within 0·07R, in Hel. Long. 207°, and that of Mars within 0·012R, in Hel. Long. 28°. This interest in the comet's path is still further increased by the speculation, due to M. Schulhof, that this comet formed originally a part of Wolf's comet, from which it possibly separated in 1815.

MEASUREMENT OF RADIAL VELOCITIES.—The methods at present employed for the measurement of the movements of the heavenly bodies towards or away from the earth usually involve the use of a comparison spectrum, whether the observations be made by eye or by photography. In special cases, however, other methods are employed, as, for example, the use of telluric lines by Duner in the measurement of the sun's rotation. It has not, however, yet been considered practicable to utilise the objective prism for the work, on account of the difficulty of obtaining reference spectra. A new method, which has the great advantage of being applicable to spectra photographed with or without slits, has recently been suggested by M. Orbinsky, of Odessa. (*Astr. Nach.* 3289.) The principle of the method is based on the fact that the displacements of lines are different at different wave-lengths, so that the distance between two lines in a spectrum depends upon the velocity of the source of light; the higher the velocity, the greater or less will be the distance between any two lines in the spectrum, according as the source of light is approaching or receding, and providing the dispersion be sufficient, it may be possible to measure the velocities by this means. Obviously the measurements are much more delicate than the direct measures of the displacements. In practice it is proposed to employ reference stars, the velocities of which have been determined in the ordinary way by photographic comparison spectra of hydrogen or iron. One of these being photographed on the same plate as the star under investigation, the results will give the velocity relatively to the comparison star, and hence the absolute velocity. The instruments employed should give the greatest possible range of wave-lengths, and it will be specially advantageous to obtain as great a difference of dispersion as possible between the extreme ends of the spectrum. It is shown by actual figures that the measurements are quite practicable, both in the case of the Potsdam spectrograph and in the objective prism employed at Harvard College. It is in the case of the latter class of instruments that the method seems most likely to be of practical value.

TWO REMARKABLE BINARY STARS.—Apart from the binary stars which can only be recognised as such by the aid of the spectroscope, the two binary stars of shortest periods at present known are κ Pegasi and δ Equulei. The orbits of these have been redetermined by Dr. See, using all available observations, many of which are due to the industry of Profs. Burnham and Barnard. The elements deduced are as follows (*Astr. Nach.* 3285, 3290):

	κ Pegasi.	δ Equulei.
P	11·42 years	11·45 years
T	1890·03	1892·8
e	0·49	0·14
a	0″·4216	0″·452
i	81°·2	79°·05
☊	110°·25	22°·2
λ	89°·2	0°·0
n	− 31°·5236	− 31°·441

Prof. Burnham has repeatedly called attention to the importance of systematic observations of rapid binaries with large telescopes, so that we should in a few years get good orbits, which in the case of most binaries would require the observations of centuries.

It will be seen that there is still a great gap between the telescopic and spectroscopic binaries, but it is quite possible that as the powers of both instruments are increased the gap may be gradually shortened from both sides.

THE SUN'S PLACE IN NATURE.[1]

VI.

WE come now to the third new point of view. Many apparent stars are really centres of nebulæ, *i.e.* of meteoritic swarms.

In that very simple statement we have perhaps the very greatest and the most fundamental change which has been suggested by the new hypothesis. I am quite certain that all of you who have read text-books of astronomy will be perfectly familiar with the statement that all stars are distant suns. I have written that myself several times, but I now know that it is not true. Some stars, instead of being distant suns like our sun, a condensed mass of gas with a crust gradually forming on it, and a thick atmosphere over it, are simply the brighter condensations, the central condensations of nebulæ, whether they be like that of Andromeda, or planetary nebulæ, or such a nebula as that of Orion. You see the idea is perfectly new and completely different from the old one, which taught us that all stars were suns. Shortly after I made this assertion, photography came to our aid, and I am so fortunate as to be able to prove to you the absolute truth of it by an appeal to Nature herself; that is, I refer for demonstration to autobiographical records with which the heavens themselves have supplied us. Among the finest and most wonderful of the nebulæ is one which, unfortunately, we do not see here, because it is in the southern hemisphere; it is that surrounding the star η in a wonderful constellation, Argo, which it is quite worth while to go south to see, were there no other reasons. From the photograph you see that there is such an intimate connection, such an obvious relation, between star and nebula, that it is impossible for us to imagine for one moment that they are not most closely and intimately connected.

FIG. 24.—Nebula round η Argus (Dr. Gill).

I will now bring before you another case which we can, all of us, see, so far as a certain part of the phenomena is concerned, and especially at this time of the year. I refer to those "stars," the six Pleiads, which you will remember once lost a sister, that one sees in the constellation of the Bull. Here they are, photographed by Dr. Roberts. You see they are not stars; they are nebulæ. What we see in this photograph (see Fig. 25), in the case of each so-called "star," is obvious; we see the centre of condensation, and more than that, it is not a simple condensation, but there are stream-lines going in all directions, and the maximum luminosity, where we locate the "star," is just at the place where, according to this photograph, the greatest number of these streams cut each other, and where, therefore, we should get the greatest possible number of collisions per second of time. The main point demonstrated by this photograph, then, is that we are not dealing with stars anything like our sun; we are simply dealing with nebulous condensations. I can show you the spectra of the brighter parts of these condensations, and you will see that they resemble the spectra of ordinary stars. Broad dark lines of hydrogen are represented in every one; hence, although we are dealing not with a star like the sun, but a meteoric condensation—a place of intersection of streams of nebulous matter—we get a spectrum such as is generally associated with the spectrum of a star. And for this there is very good reason.

Here an interesting point comes in. Suppose that we wished to observe spectroscopically what was going on in these condensations, and that I allow the image of one of them to fall on the slit of the spectroscope, so that we have the condensation at the centre, and the ends of the slit of the spectroscope beyond the condensation. At the centre, where the slit crosses the condensation, of course we should have the spectrum which you have already seen on the screen, a spectrum indicating that there is something there which gives us a continuous spectrum, *i.e.* one rich in all the colours of the rainbow; but that some of the light is absorbed here and there in consequence of the surrounding atmosphere of hydrogen gas. So much for the centre. Next consider what will happen when I observe, for instance, this or that part of the nebula where the condensation is absent; we shall not get absorption phenomena, but we shall get radiation phenomena, and therefore a long bright line representing the radiation of hydrogen over a large area, and at the middle of it the ordinary spectrum of a star. Prof. Campbell, at the Lick Observatory, has recently subjected another star to a similar treatment, and you will see (Fig. 26) what he has found. By putting the slit of the spectroscope upon the image of the star, he finds that he gets the spectrum from one end to the other; but you see that at the place occupied by one of the hydrogen lines he gets a much longer image of the slit, showing that he had to deal there with a star immersed in something which was competent to give a spectrum of hydrogen. What was that something? You can understand perfectly well that, if one of the Pleiads had been examined in the same way, it would be quite possible that we should get just such an appearance as Prof. Campbell was fortunate enough to obtain. This raises an interesting question, in which astronomic thought has been going up and down now for the last fourteen or fifteen years, and I think I can show you exactly how the matter lies. The diameter of the sun is very nearly a million miles. Now, suppose that the diameter of the solar atmosphere was ten million miles; then if we were by any means whatever to spectroscopically examine the image of the sun under such conditions that all the light coming from these different regions could enter the slit of the spectroscope at the same time, and give us, added together, the whole light, we should be able to determine practically what we might be able to see under these conditions by some such considerations as these:—

Diameter of the sun, one million miles.

Diameter of the sun's atmosphere, ten million miles.

We should therefore get the light from the sun in the ratio of 1 to 99 of the light from the atmosphere. Now suppose that there is any chemical connection between the absorption in the light of the sun and the radiation in the light of the sun's atmosphere, if we sweep the slit of the spectroscope along the edge of the sun, the part of the spectrum which writes for us what is going on in the solar photosphere, gives us the spectrum crossed by dark lines; the effect of the atmosphere is to absorb the light of the more distant sun at which we look, and the result of the absorption is to give us dark lines.

But when we look at the atmosphere which is resting on the edge of the sun, and look at it where there is no brighter sun behind, absorption no longer comes into play, and we get bright lines. This is what happens when we look at the solar atmosphere above the sun's edge and the solar atmosphere between us and the sun. So long as we are telling the story of the sun, we get

[1] Revised from shorthand notes of a course of Lectures to Working Men at the Museum of Practical Geology during November and December, 1894. (Continued from page [illegible].)

the dark lines; so long as we are telling the story of the sun's atmosphere, we get bright lines.

We found that the area from which the sunlight comes to us is represented by 1, whereas the area from which the atmospheric light comes to us is represented by 99: so that if the light of the atmosphere is very much dimmer than the light of the central sun, in consequence of its enormous area we may get some light from it intermingled with the light of the sun itself in our spectroscopes.

Therefore, when we look at the complete spectrum, we may lose the dark hydrogen lines in the spectrum of the star, and we may get bright lines instead of dark ones for every line in the spectrum of a star which is filled up by the absorption of a substance the line of which may be seen bright in the spectrum of that star's atmosphere. Thus there is the possibility that when we have to deal with bright lines in the spectrum of an apparent star, we may be dealing with the atmosphere of the star. You will at once see that; if we are dealing with a pure meteoric agglomeration, then of course we shall get that appearance beyond all possible question.

FIG. 25. The Pleiades (Dr. Roberts).

Now, let me give you one or two cases showing you how this thing works out. The strongest case would be that we should get the bright hydrogen lines putting out the dark hydrogen lines, so that if we got a class of stars without any dark hydrogen lines, we should be justified in supposing that those stars had an enormous atmosphere of hydrogen, and that the fainter bright lines from the larger area just cancelled the effect of the other light from the very much smaller area. Another way that we might expect this thing to work would be that we should not get the bright hydrogen lines entirely putting out the dark hydrogen lines, but that we should get a thinner line in the centre of a broader dark one. Now, that really happens in several stars in the heavens.

I give in Fig. 27 untouched photographs of a star in Orion, and a star in Cassiopeiæ. The latter is very like the star in Orion, because all the absorption lines are common to the two stars; but I may point out to you that we get a bright hydrogen line running down the centre of the dark ones. We may have such an effect produced either by a star having an enormous atmosphere, or by the star with which we are dealing being simply the central condensation of an enormous nebula.

FIG. 26. Prof. Campbell's observation of the F line of hydrogen in the spectrum of a bright line star.

I am bound to say that when I began this work in 1876, I was under the impression that such phenomena were due only to the effects of the atmosphere. But one lives and learns, and since then I have come to the conclusion that that explanation is not the best one, and that when we get such phenomena as those you now see on the screen, we have really to deal with the central condensations of nebulous swarms. I do not hesitate to bring these facts before you, because it is particularly in this connection of thought and experiment and comparison that whatever progress which is now being made in astronomical science is being secured.

Associated with this view we have the statement that stars with bright lines are closely associated with nebulæ, as evidenced by their structure. You will see that there is one method which enables us to compare the bright lines in stars like γ Cassiopeiæ with the nebulæ, as it gives us an opportunity of determining whether or not the bright lines seen in the so-called bright-line stars are or are not the same as the bright lines seen in nebulæ. In the first inquiry in this direction, which consisted of a statistical statement of the number of times certain lines were seen in the spectra, both of nebulæ and of bright-line stars, it was stated that nine lines were coincident, and that and other work done about that time was of such a very trenchant nature that Prof. Pickering, who is one of our very highest authorities in all these matters, accepted at once the grouping together of stars having bright lines in their spectra with the nebulæ. That, you see, was another very definite step in advance indeed.

I can show you a map giving you the evidence of this kind which has been brought into court. We have in it the lines seen in the spectrum of the nebula of Orion, and the longer the line is the stronger it is in the photograph. Then we have underneath the lines recorded in the Orion stars, in the bright line stars, and in the planetary nebulæ; and if you will cast your eyes down these chief lines, you will see that there is a considerable number of lines common to all these bodies.

That is the kind of evidence on which we have been compelled to rely to answer the question: Is there any chemical relationship, and therefore physical relationship, between the bright line stars and the nebula of Orion? And you see the evidence is very strongly in favour of an affirmative statement. Not only does Prof. Pickering accept it, but Prof. Keeler also confirms it. He says the spectra of the planetary nebulæ have a remarkable resemblance to the bright line stars.

But even more fortunate for us than all this is the fact that Prof. Campbell has just finished a most important and laborious

study of these stars at the Lick Observatory, and has observed all the lines in the spectra of a much greater number of stars than was available when I began the inquiry; his measurements are very much more accurate than any that were possible then to me. What happens when we come to deal with his results? The thing is a thousand times more convincing than it ever was. When we take Campbell's list, we get very many more coincidences than we had when we dealt with Pickering's. So that, the further we go in this inquiry, the greater is the number of coincidences. I told you that in the first inquiry there were nine coincidences observed; now we get nineteen coincidences out of thirty-three. We are therefore justified in saying that the more these phenomena are observed, the more closely associated are they seen to be.

Let us take the case of one of the brightest stars of this class in Argo, the spectrum of a star which my friend Respighi and myself were the first to see on a very hot night in Madras in 1871, a beautiful spectrum with many bright lines. Now, here these bright lines are indicated in the diagram, and we find by attempting to study their real positions that some of them are due to carbon, and some of them to iron, and some of them to sodium. Prof. Campbell has recently included the study of this star in his work at Lick, and everything that he has done there seems to confirm the idea. The great question is the question of carbon. You know the importance of carbon in a star like this, because we have had carbon differentiating comets from nebulæ, and finally the discovery of carbon in the nebulæ.

I have some apparatus here to show you, which illustrates what one has to do in studying the spectrum of carbon; we must not only deal with it in its ordinary form, and observe the spectrum as seen in the Bunsen flame, and so on, but we must get different compounds of carbon, and expose them to different temperatures and different pressures. That has been done by myself and others; during the last twenty years I suppose I have made thousands of observations on the spectrum of carbon in different forms and conditions.

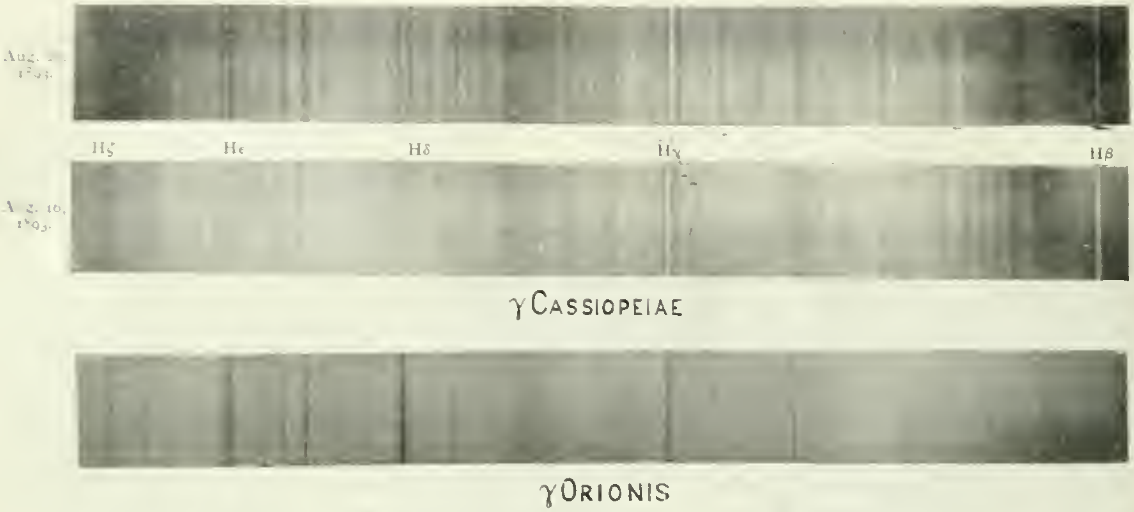

FIG. 27.—Spectra of γ Cassiopeiae and Bellatrix, from photographs taken at South Kensington.

Fig. 28 shows a series of photographs of the same carbon compound in the same tube, taken under different conditions; you will see that there is a very considerable difference in the intensity of the same bands, as the pressure of the gas has been changed; the particular part of one of the bands which you see enhanced seems to be playing a rôle of considerable importance in the spectra of some of these stars.

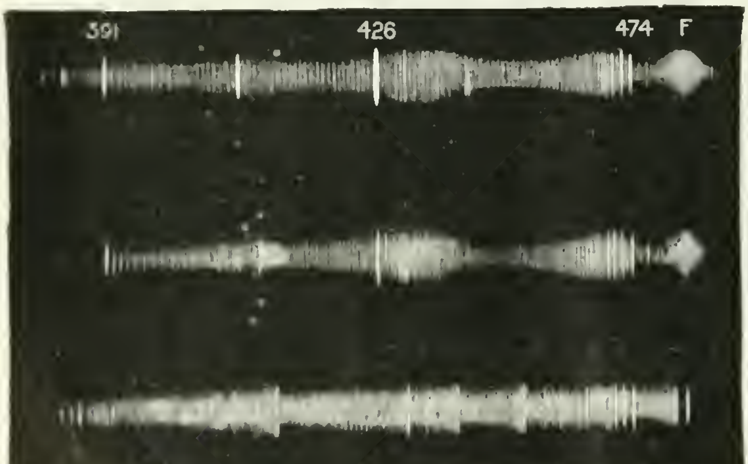

FIG. 28.—Spectrum of carbon at different temperatures.

This is shown merely as an indication of the kind of minute work which is absolutely essential to determine what is happening in the chemical elements in these bodies.

J. NORMAN LOCKYER.

(To be continued.)

THE MANAGEMENT OF EPPING FOREST.

AS a sequel to the continued agitation in the newspapers about Epping Forest, a deputation was received by the Committee at their meeting on Tuesday last at the Guildhall. The object of the deputation was to present the following memorial:—

"Your memorialists have heard with grave concern that your Committee have been urged to put a stop to all further removals of trees in Epping Forest for a period of years. The undersigned have examined the area in question and are of opinion that such a resolution, if sanctioned by your Committee, would be productive of undoubted injury to the Forest, especially as regards those portions of Loughton, Epping, Waltham and Sewardstone Manors which are covered with a dense growth of pollarded trees.

"Those who have approached you with the request to which we have referred do not appear to have apprehended the altered

conditions which were brought about by the arrest of pollarding enacted in 1878.

"Many of these pollards, whether single trees or groups, are capable of picturesque development, but only under healthy conditions and with adequate space. To leave them all to grow together—several hundreds to the acre—will lead to mutual destruction, while the continuous overhead shade destroys the undergrowth and the varied vegetation which constitutes the chief charm of a forest and the hope of its reproduction in the future.

"The evils we have indicated are already sufficiently manifest, and it must be obvious to all competent observers that, unless timely steps are taken, a few years' further growth must produce a singularly monotonous, artificial, and unhealthy result.

"Some of us have been familiar with the Forest for many years, and can certify to the great improvement and the increase of natural growth which has already resulted from the operations of your Committee, now continued for many years."

The following signatures were attached:—The Earl of Gainsborough, Viscount Powerscourt, Lords Northbourne, Rayleigh (Lord Lieutenant of Essex) and Walsingham, Sir John Lubbock, Sir W. H. Flower, Right Hon. J. Bryce (President of the Board of Trade), Right Hon. G. Shaw Lefevre (President Local Government Board), Mr. Justice Wills, Sir Robert Hunter (Solicitor to the Post Office), Prof. G. S. Boulger, Mr. Horace T. Brown, Mr. F. Chancellor (Mayor of Chelmsford), Mr. W. Cole (Secretary to the Essex Field Club), Dr. M. C. Cooke, Prof. J. B. Farmer, Prof. W. R. Fisher (Royal Indian Engineering College), Mr. W. Forbes (Agent to the Duke of Richmond and Gordon), Mr. F. Carruthers Gould, Mr. J. E. Harting, Mr. T. V. Holmes, Mr. David Howard (President of the Essex Field Club), Mr. Andrew Johnston (Chairman of the Essex County Council), Mr. H. Joslin (High Sheriff of Essex), Mr. T. Kemble, Colonel Lockwood, M.P., Dr. Maxwell Masters, Prof. R. Meldola, Mr. Briton Riviere, R.A., Prof. E. B. Poulton, Mr. A. Savill, Prof. Stewart, Mr. W. White (Curator of the Ruskin Museum).

The following memorial, bearing the signatures of about forty residents in the Forest district, was at the same time presented:—

"We, the undersigned, being residents in the Forest parishes, beg to state that we have witnessed with satisfaction a great improvement in the aspect of the Forest directly due to the removal, during the past sixteen years, of inferior stems, and to the consequent advance in beauty of those that remain, as well as the encouragement of healthy young growth. We are certain that it will be an irreparable misfortune if the careful thinning which has been hitherto carried out is not steadily continued.

"We further beg to assure the Committee that in our opinion the operations in Hawk Wood, so far from being excessive, still fall short of what is required for the healthy growth of oak trees.

"In Monk Wood there is already a marked improvement following on your removal, eighteen months ago, of a proportion of the poorest pollarded trees. The same is true, even in a more marked degree, of Lord's Bushes. We believe that, if the gentlemen who have appeared as critics of your management were to judge of it by the appearance of the portions thinned three or four years after thinning, instead of immediately after, when they necessarily have a bare and unattractive effect, they would themselves be of a different opinion.

"In conclusion, we beg to assure you that the view that the action of the Committee has been destructive is not entertained by those living on the spot who are most qualified to judge."

The deputations were formally introduced by the Chairman of the Essex Council, and the first memorial was presented by Prof. Meldola. The Committee was addressed also by Sir Robert Hunter, Prof. Boulger, and Mr. F. C. Gould. After these representations the public may safely disregard all future expressions of irresponsible and unskilled opinions in the press. The Chairman of the Committee assured the deputation that their policy would not be influenced by such criticisms.

SCIENCE IN THE MAGAZINES.

MR. HERBERT SPENCER'S second article on "Professional Institutions" appears in the *Contemporary*. The article deals with the intimate relation between the priest and the medicine-man of early societies, and shows how the physician was originated from the priest. Many proofs are given that medical treatment was long associated with priestly functions, and that the uncultured mind still believes in some of the methods of the primitive medicine-man. Mr. Spencer has also an article in the *Fortnightly*, in which he exhibits the insecure base upon which Mr. Balfour has laid his "Foundations of Belief," and describes that distinguished author's dialectic efforts, as well as Lord Salisbury's address to the British Association at Oxford, as sacrificial offerings of effigies to an apotheosised public. Neither one nor the other have produced the faintest impression in the world of science. Another article which may interest our readers, deals with University degrees for women, the writer comparing the action of Göttingen, in recently granting a degree to Miss Chisholm, with the policy of Oxford and Cambridge Universities as to women students.

In a superbly illustrated paper, entitled "The Discovery of Glacier Bay," that veteran explorer Mr. John Muir gives, in the *Century*, an account of his journey to the now famous Glacier Bay of Alaska, in 1879. The great public library in Boston is described in the same magazine: its artistic aspects by Mrs. S. Van Rensselaer, and its ideals and working conditions by Mr. Lindsay Swift.

That fluent writer Eha, the author of "A Naturalist on the Prowl" and other equally attractive works, contributes a short paper, entitled "Voices of the Indian Night," to the *Sunday Magazine*. Ethnologists may be interested in an article by Miss A. Spinner in the *National*, on beliefs concerning "Duppies" prevalent in the West Indies. A "Duppy" is not simply the negro equivalent for a ghost, but is regarded as the shadow of the departed.

There are two popularly-written papers in *Longman's*, one, of a Selbornian character, by Mr. H. G. Hutchinson, and another concerned with the natural processes involved in the evolution of soil in general, and golf-links in particular, by Dr. Edward Blake.

Science Gossip has among its articles one on explosions in electric light mains, by Mr. J. A. Wanklyn and Mr. W. J. Cooper, and some suggestions with reference to the work of a scientific society, by the Rev. H. N. Hutchinson. *Chambers's Journal* contains short papers on soluble paper, Scottish goldfields, forest dwarfs of the Congo, and the habits and tastes of Lepidoptera. *Scribner* has some common-sense remarks, by Dr. J. W. Roosevelt, on cycling from a physiological point of view.

We have received, in addition to the magazines named in the foregoing, *Humanitarian* and *Good Words*, but no articles in them call for comment here.

ARGON.[1]

IT is some three or four years since I had the honour of lecturing here one Friday evening upon the densities of oxygen and hydrogen gases, and upon the conclusions that might be drawn from the results. It is not necessary, therefore, that I should trouble you to-night with any detail as to the method by which gases can be accurately weighed. I must take that as known, merely mentioning that it is substantially the same as is used by all investigators nowadays, and introduced more than fifty years ago by Regnault. It was not until after that lecture that I turned my attention to nitrogen; and in the first instance I employed a method of preparing the gas which originated with Mr. Vernon Harcourt, of Oxford. In this method the oxygen of ordinary atmospheric air is got rid of with the aid of ammonia. Air is bubbled through liquid ammonia, and then passed through a red-hot tube. In its passage the oxygen of the air combines with the hydrogen of the ammonia, all the oxygen being in that way burnt up and converted into water. The excess of ammonia is subsequently absorbed with acid, and the water by ordinary desiccating agents. That method is very convenient; and, when I had obtained a few concordant results by means of it, I thought that the work was complete, and that the weight of nitrogen was satisfactorily determined. But then I reflected that it is always advisable to employ more than one method, and that the method that I had used—Mr. Vernon Harcourt's method—was not that which had been used by any of those who had preceded me in weighing nitrogen. The usual method consists in absorbing the oxygen of air by means of red-hot copper; and I thought that I ought at least to give that method

[1] A discourse delivered at the Royal Institution on Friday, April 5, by the Right Hon. Lord Rayleigh, F.R.S.

a trial, fully expecting to obtain forthwith a value in harmony with that already afforded by the ammonia method. The result, however, proved otherwise. The gas obtained by the copper method, as I may call it, proved to be one-thousandth part heavier than that obtained by the ammonia method; and, on repetition, that difference was only brought out more clearly. This was about three years ago. Then, in order, if possible, to get further light upon a discrepancy which puzzled me very much, and which, at that time, I regarded only with disgust and impatience, I published a letter in NATURE inviting criticisms from chemists who might be interested in such questions. I obtained various useful suggestions, but none going to the root of the matter. Several persons who wrote to me privately were inclined to think that the explanation was to be sought in a partial dissociation of the nitrogen derived from ammonia. For, before going further, I ought to explain that, in the nitrogen obtained by the ammonia method, some—about a seventh part—is derived from the ammonia, the larger part, however, being derived as usual from the atmosphere. If the chemically derived nitrogen were partly dissociated into its component atoms, then the lightness of the gas so prepared would be explained.

The next step in the inquiry was, if possible, to exaggerate the discrepancy. One's instinct at first is to try to get rid of a discrepancy, but I believe that experience shows such an endeavour to be a mistake. What one ought to do is to magnify a small discrepancy with a view to finding out the explanation: and, as it appeared in the present case that the root of the discrepancy lay in the fact that part of the nitrogen prepared by the ammonia method was nitrogen out of ammonia, although the greater part remained of common origin in both cases, the application of the principle suggested a trial of the weight of nitrogen obtained wholly from ammonia. This could easily be done by substituting pure oxygen for atmospheric air in the ammonia method, so that the whole, instead of only a part, of the nitrogen collected should be derived from the ammonia itself. The discrepancy was at once magnified some five times. The nitrogen so obtained from ammonia proved to be about one-half per cent. lighter than nitrogen obtained in the ordinary way from the atmosphere, and which I may call for brevity "atmospheric" nitrogen.

That result stood out pretty sharply from the first: but it was necessary to confirm it by comparison with nitrogen chemically derived in other ways. The table before you gives a summary of such results, the numbers being the weights in grams actually contained under standard conditions in the globe employed.

ATMOSPHERIC NITROGEN.

By hot copper (1892)	2·3103
By hot iron (1893)	2·3100
By ferrous hydrate (1894)	2·3102
Mean	2·3102

CHEMICAL NITROGEN.

From nitric oxide	2·3001
From nitrous oxide	2·2990
From ammonium nitrite purified at a red heat ...	2·2987
From urea	2·2985
From ammonium nitrite purified in the cold ...	2·2987
Mean	2·2990

The difference is about 11 milligrams, or about one-half per cent.; and it was sufficient to prove conclusively that the two kinds of nitrogen—the chemically derived nitrogen and the atmospheric nitrogen—differed in weight, and therefore, of course, in quality, for some reason hitherto unknown.

I need not spend time in explaining the various precautions that were necessary in order to establish surely that conclusion. One had to be on one's guard against impurities, especially against the presence of hydrogen, which might seriously lighten any gas in which it was contained. I believe, however, that the precautions taken were sufficient to exclude all questions of that sort, and the result, which I published about this time last year, stood sharply out, that the nitrogen obtained from chemical sources was different from the nitrogen obtained from the air.

Well, that difference, admitting it to be established, was sufficient to show that some hitherto unknown gas is involved in the matter. It might be that the new gas was dissociated nitrogen, contained in that which was too light, the chemical nitrogen—and at first that was the explanation to which I leaned; but certain experiments went a long way to discourage such a supposition. In the first place, chemical evidence—and in this matter I am greatly dependent upon the kindness of chemical friends—tends to show that, even if ordinary nitrogen could be dissociated at all into its component atoms, such atoms would not be likely to enjoy any very long continued existence. Even ozone goes slowly back to the more normal state of oxygen: and it was thought that dissociated nitrogen would have even a greater tendency to revert to the normal condition. The experiment suggested by that remark was as follows—to keep chemical nitrogen—the too light nitrogen which might be supposed to contain dissociated molecules—for a good while, and to examine whether it changed in density. Of course it would be useless to shut up gas in a globe and weigh it, and then, after an interval, to weigh it again, for there would be no opportunity for any change of weight to occur, even although the gas within the globe had undergone some chemical alteration. It is necessary to re-establish the standard conditions of temperature and pressure which are always understood when we speak of filling a globe with gas, for I need hardly say that filling a globe with gas is but a figure of speech. Everything depends upon the temperature and pressure at which you work. However, that obvious point being borne in mind, it was proved by experiment that the gas did not change in weight by standing for eight months—a result tending to show that the abnormal lightness was not the consequence of dissociation.

Further experiments were tried upon the action of the silent electric discharge—both upon the atmospheric nitrogen and upon the chemically derived nitrogen—but neither of them seemed to be sensibly affected by such treatment; so that, altogether, the balance of evidence seemed to incline against the hypothesis of abnormal lightness in the chemically derived nitrogen being due to dissociation, and to suggest strongly, as almost the only possible alternative, that there must be in atmospheric nitrogen some constituent heavier than true nitrogen.

At that point the question arose, What was the evidence that all the so-called nitrogen of the atmosphere was of one quality? And I remember—I think it was about this time last year, or a little earlier—putting the question to my colleague Prof. Dewar. His answer was that he doubted whether anything material had been done upon the matter since the time of Cavendish, and that I had better refer to Cavendish's original paper. That advice I quickly followed, and I was rather surprised to find that Cavendish had himself put this question quite as sharply as I could put it. Translated from the old-fashioned phraseology connected with the theory of phlogiston, his question was whether the inert ingredient of the air is really all of one kind; whether all the nitrogen of the air is really the same as the nitrogen of nitre. Cavendish not only asked himself this question, but he endeavoured to answer it by an appeal to experiment.

I should like to show you Cavendish's experiment in something like its original form. He inverted a U tube filled with mercury, the legs standing in two separate mercury cups. He then passed up, so as to stand above the mercury, a mixture of nitrogen, or of air, and oxygen; and he caused an electric current from a frictional electrical machine like the one I have before me to pass from the mercury in the one leg to the mercury in the other, giving sparks across the intervening column of air. I do not propose to use a frictional machine to-night, but I will substitute for it one giving electricity of the same quality of the construction introduced by Mr. Wimshurst, of which we have a fine specimen in the Institution. It stands just outside the door of the theatre, and will supply an electric current along insulated wires, leading to the mercury cups; and, if we are successful, we shall cause sparks to pass through the small length of air included above the columns of mercury. There they are; and after a little time you will notice that the mercury rises, indicating that the gas is sensibly absorbed under the influence of the sparks and of a piece of potash floating on the mercury. It was by that means that Cavendish established his great discovery of the nature of the inert ingredient in the atmosphere, which we now call nitrogen; and, as I have said, Cavendish himself proposed the question, as distinctly as we can do, Is this inert ingredient all of one kind? and he proceeded to test that question. He found, after days and weeks of protracted experiment, that, for the most part, the nitrogen of the atmosphere absorbed in this manner, was converted into nitrous acid; but that there was a small residue remaining after prolonged treatment with sparks, and a final absorption of the residual oxygen. That residue

amounted to about $\frac{1}{120}$ part of the nitrogen taken; and Cavendish draws the conclusion that if there be more than one inert ingredient in the atmosphere, at any rate the second ingredient is not contained to a greater extent than $\frac{1}{120}$ part.

I must not wait too long over the experiment. Mr. Gordon tells me that a certain amount of contraction has already occurred; and if we project the U upon the screen, we shall be able to verify the fact. It is only a question of time for the greater part of the gas to be taken up, as we have proved by preliminary experiments.

In what I have to say from this point onwards, I must be understood as speaking as much on behalf of Prof. Ramsay as for myself. At the first, the work which we did was to a certain extent independent. Afterwards we worked in concert, and all that we have published in our joint names must be regarded as being equally the work of both of us. But, of course, Prof. Ramsay must not be held responsible for any chemical blunder into which I may stumble to-night.

By his work and by mine the heavier ingredient in atmospheric nitrogen which was the origin of the discrepancy in the densities has been isolated, and we have given it the name of "argon." For this purpose we may use the original method of Cavendish, with the advantages of modern appliances. We can procure more powerful electric sparks than any which Cavendish could command by the use of the ordinary Ruhmkorff coil stimulated by a battery of Grove cells; and it is possible so to obtain evidence of the existence of argon. The oxidation of nitrogen by that method goes on pretty quickly. If you put some ordinary air, or, better still, a mixture of air and oxygen, in a tube in which electric sparks are made to pass for a certain time, then in looking through the tube you observe the well-known reddish-orange fumes of the oxides of nitrogen. I will not take up time in going through the experiment, but will merely exhibit a tube already prepared (image on screen).

One can work more efficiently by employing the alternate currents from dynamo machines which are now at our command. In this Institution we have the advantage of a public supply; and if I pass alternate currents originating in Deptford through this Ruhmkorff coil, which acts as what is now called a "high potential transformer," and allow sparks from the secondary to pass in an inverted test tube between platinum points, we shall be able to show in a comparatively short time a pretty rapid absorption of the gases. The electric current is led into the working chamber through bent glass tubes containing mercury, and provided at their inner extremities with platinum points. In this arrangement we avoid the risk, which would otherwise be serious, of a fracture just when we least desired it. I now start the sparks by switching on the Ruhmkorff to the alternate current supply; and, if you will take note of the level of the liquid representing the quantity of mixed gases included, I think you will see after, perhaps, a quarter of an hour that the liquid has very appreciably risen, owing to the union of the nitrogen and the oxygen gases under the influence of the electrical discharge, and subsequent absorption of the resulting compound by the alkaline liquid with which the gas space is enclosed.

By means of this little apparatus, which is very convenient for operations upon a moderate scale, such as for analyses of "nitrogen" for the amount of argon that it may contain, we are able to get an absorption of about 80 cubic centimetres per hour) or about 4 inches along this test tube, when all is going well. In order, however, to obtain the isolation of argon on any considerable scale by means of the oxygen method, we must employ an apparatus still more enlarged. The isolation of argon requires the removal of nitrogen, and, indeed, of very large quantities of nitrogen, for, as it appears, the proportion of argon contained in atmospheric nitrogen is only about 1 per cent., so that for every litre of argon that you wish to get you must eat up some hundred litres of nitrogen. That, however, can be done upon an adequate scale by calling to our aid the powerful electric discharge now obtainable by means of the alternate current supply and high potential transformers.

In what I have done upon this subject I have had the advantage of the advice of Mr. Crookes, who some years ago drew special attention to the electric discharge or flame, and showed that many of its properties depended upon the fact that it had the power of causing, upon a very considerable scale, a combination of the nitrogen and the oxygen of the air in which it was made.

I had first thought of showing in the lecture room the actual apparatus which I have employed for the concentration of argon; but the difficulty is that, as the apparatus has to be used, the working parts are almost invisible, and I came to the conclusion that it would really be more instructive as well as more convenient to show the parts isolated, a very little effort of imagination being then all that is required in order to reconstruct in the mind the actual arrangements employed.

First, as to the electric arc or flame itself. We have here a transformer made by Pike and Harris. It is not the one that I have used in practice; but it is convenient for certain purposes, and it can be connected by means of a switch with the alternate currents of 100 volts furnished by the Supply Company. The platinum terminals that you see here are modelled exactly upon the plan of those which have been employed in practice. I may say a word or two on the question of mounting. The terminals require to be very massive on account of the heat evolved. In this case they consist of platinum wire doubled upon itself six times. The platinums are continued by iron wires going through glass tubes, and attached at the ends to the copper leads. For better security, the tubes themselves are stopped at the lower ends with corks and charged with water, the advantage being that, when the whole arrangement is fitted by means of an indiarubber stopper into a closed vessel, you have a witness that, as long as the water remains in position, no leak can have occurred through the insulating tubes conveying the electrodes.

Now, if we switch on the current and approximate the points sufficiently, we get the electric flame. There you have it. It is, at present, showing a certain amount of soda. That in time would burn off. After the arc has once been struck, the platinums can be separated; and then you have two tongues of fire ascending almost independently of one another, but meeting above. Under the influence of such a flame, the oxygen and the nitrogen of the air combine at a reasonable rate, and in this way the nitrogen is got rid of. It is now only a question of boxing up the gas in a closed space, where the argon concentrated by the combustion of the nitrogen can be collected. But there are difficulties to be encountered here. One cannot well use anything but a glass vessel. There is hardly any metal available that will withstand the action of strong caustic alkali and of the nitrous fumes resulting from the flame. One is practically limited to glass. The glass vessel employed is a large flask with a single neck, about half full of caustic alkali. The electrodes are carried through the neck by means of an indiarubber bung provided also with tubes for leading in the gas. The electric flame is situated at a distance of only about half an inch above the caustic alkali. In that way an efficient circulation is established; the hot gases as they rise from the flame strike the top, and then as they come round again in the course of the circulation they pass sufficiently close to the caustic alkali to ensure an adequate removal of the nitrous fumes.

There is another point to be mentioned. It is necessary to keep the vessel cool; otherwise the heat would soon rise to such a point that there would be excessive generation of steam, and then the operation would come to a standstill. In order to meet this difficulty the upper part of the vessel is provided with a water-jacket, in which a circulation can be established. No doubt the glass is severely treated, but it seems to stand it in a fairly amiable manner.

By means of an arrangement of this kind, taking nearly three-horse power from the electric supply, it is possible to consume nitrogen at a reasonable rate. The transformers actually used are the "Hedgehog" transformers of Mr. Swinburne, intended to transform from 100 volts to 2400 volts. By Mr. Swinburne's advice I have used two such, the fine wires being in series so as to accumulate the electrical potential and the thick wires in parallel. The rate at which the mixed gases are absorbed is about seven litres per hour; and the apparatus, when once fairly started, works very well as a rule, going for many hours without attention. At times the arc has a trick of going out, and it then requires to be restarted by approximating the platinums. We have already worked fourteen hours on end, and by the aid of one or two automatic appliances it would, I think, be possible to continue operations day and night.

The gases, air and oxygen in about equal proportions, are mixed in a large gasholder, and are fed in automatically as required. The argon gradually accumulates: and when it is desired to stop operations the supply of nitrogen is cut off, and only pure oxygen allowed admittance. In this way the remaining nitrogen is consumed, so that, finally, the working vessel is charged with a mixture of argon and oxygen only, from which

the oxygen is removed by ordinary well-known chemical methods. I may mention that at the close of the operation, when the nitrogen is all gone, the arc changes its appearance, and becomes of a brilliant blue colour.

I have said enough about this method, and I must now pass on to the alternative method which has been very successful in Prof. Ramsay's hands—that of absorbing nitrogen by means of red-hot magnesium. By the kindness of Prof. Ramsay and Mr. Matthews, his assistant, we have here the full scale apparatus before us almost exactly as they use it. On the left there is a reservoir of nitrogen derived from air by the simple removal of oxygen. The gas is then dried. Here it is bubbled through sulphuric acid. It then passes through a long tube made of hard glass and charged with magnesium in the form of thin turnings. During the passage of the gas over the magnesium at a bright red heat, the nitrogen is absorbed in a greater degree, and the gas which finally passes through is immensely richer in argon than that which first enters the hot tube. At the present time you see a tolerably rapid bubbling on the left, indicative of the flow of atmospheric nitrogen into the combustion furnace; whereas, on the right, the outflow is very much slower. Care must be taken to prevent the heat rising to such a point as to soften the glass. The concentrated argon is collected in a second gas-holder, and afterwards submitted to further treatment. The apparatus employed by Prof. Ramsay in the subsequent treatment is exhibited in the diagram, and is very effective for its purpose; but I am afraid that the details of it would not readily be followed from any explanation that I could give in the time at my disposal. The principle consists in the circulation of the mixture of nitrogen and argon over hot magnesium, the gas being made to pass round and round until the nitrogen is effectively removed from it. At the end that operation, as in the case of the oxygen method, proceeds somewhat slowly. When the greater part of the nitrogen is gone, the remainder seems to be unwilling to follow, and it requires somewhat protracted treatment in order to be sure that the nitrogen has wholly disappeared. When I say "wholly disappeared," that, perhaps, would be too much to say in any case. What we can say is that the spectrum test is adequate to show the presence, or at any rate to show the addition, of about $1\frac{1}{2}$ per cent. of nitrogen to argon as pure as we can get it; so that it is fair to argue that any nitrogen at that stage remaining in the argon is only a small fraction of $1\frac{1}{2}$ per cent.

I should have liked at this point to be able to give advice as to which of the two methods—the oxygen method or the magnesium method—is the easier and the more to be recommended; but I confess that I am quite at a loss to do so. One difficulty in the comparison arises from the fact that they have been in different hands. As far as I can estimate, the quantities of nitrogen eaten up in a given time are not very different. In that respect, perhaps, the magnesium method has some advantage; but, on the other hand, it may be said that the magnesium process requires a much closer supervision, so that, perhaps, fourteen hours of the oxygen method may not unfairly compare with eight hours or so of the magnesium method. In practice a great deal would depend upon whether in any particular laboratory alternate currents are available from a public supply. If the alternate currents are at hand, I think it may probably be the case that the oxygen method is the easier; but, otherwise, the magnesium method would, probably, be preferred, especially by chemists who are familiar with operations conducted in red-hot tubes.

I have here another experiment illustrative of the reaction between magnesium and nitrogen. Two rods of that metal are suitably mounted in an atmosphere of nitrogen, so arranged that we can bring them into contact and cause an electric arc to form between them. Under the action of the heat of the electric arc the nitrogen will combine with the magnesium; and if we had time to carry out the experiment we could demonstrate a rapid absorption of nitrogen by this method. When the experiment was first tried, I had hoped that it might be possible, by the aid of electricity, to start the action so effectively that the magnesium would continue to burn independently under its own developed heat in the atmosphere of nitrogen. Possibly, on a larger scale, something of this sort might succeed, but I bring it forward here only as an illustration. We turn on the electric current, and bring the magnesiums together. You see a brilliant green light, indicating the vaporisation of the magnesium. Under the influence of the heat the magnesium burns, and there is collected in the glass vessel a certain amount of brownish-looking powder which consists mainly of the nitride of magnesium. Of course, if there is any oxygen present it has the preference, and the ordinary white oxide of magnesium is formed.

The gas thus isolated is proved to be inert by the very fact of its isolation. It refuses to combine under circumstances in which nitrogen, itself always considered very inert, does combine—both in the case of the oxygen treatment and in the case of the magnesium treatment; and these facts are, perhaps, almost enough to justify the name which we have suggested for it. But, in addition to this, it has been proved to be inert under a considerable variety of other conditions such as might have been expected to tempt it into combination. I will not recapitulate all the experiments which have been tried, almost entirely by Prof. Ramsay, to induce the gas to combine. Hitherto, in our hands, it has not done so; and I may mention that recently, since the publication of the abstract of our paper read before the Royal Society, argon has been submitted to the action of titanium at a red heat, titanium being a metal having a great affinity for nitrogen, and that argon has resisted the temptation to which nitrogen succumbs. We never have asserted, and we do not now assert, that argon can under no circumstances be got to combine. That would, indeed, be a rash assertion for any one to venture upon; and only within the last few weeks there has been a most interesting announcement by M. Berthelot, of Paris, that, under the action of the silent electric discharge, argon can be absorbed when treated in contact with the vapour of benzine. Such a statement, coming from so great an authority, commands our attention; and if we accept the conclusions, as I suppose we must do, it will follow that argon has, under those circumstances, combined.

Argon is rather freely soluble in water. That is a thing that troubled us at first in trying to isolate the gas; because, when one was dealing with very small quantities, it seemed to be always disappearing. In trying to accumulate it we made no progress. After a sufficient quantity had been prepared, special experiments were made on the solubility of argon in water. It has been found that argon, prepared both by the magnesium method and by the oxygen method, has about the same solubility in water as oxygen—some two-and-a-half times the solubility of nitrogen. This suggests, what has been verified by experiment, that the dissolved gases of water should contain a larger proportion of argon than does atmospheric nitrogen. I have here an apparatus of a somewhat rough description, which I have employed in experiments of this kind. The boiler employed consists of an old oil-can. The water is supplied to it and drawn from it by coaxial tubes of metal. The incoming cold water flows through the outer annulus between the two tubes. The outgoing hot water passes through the inner tube, which ends in the interior of the vessel at a higher level. By means of this arrangement the heat of the water which has done its work is passed on to the incoming water not yet in operation, and in that way a limited amount of heat is made to bring up to the boil a very much larger quantity of water than would otherwise be possible, the greater part of the dissolved gases being liberated at the same time. These are collected in the ordinary way. What you see in this flask is dissolved air collected out of water in the course of the last three or four hours. Such gas, when treated as if it were atmospheric nitrogen, that is to say after removal of the oxygen and minor impurities, is found to be decidedly heavier than atmospheric nitrogen to such an extent as to indicate that the proportion of argon contained is about double. It is obvious, therefore, that the dissolved gases of water form a convenient source of argon, by which some of the labour of separation from air is obviated. During the last few weeks I have been supplied from Manchester by Mr. Macdougall, who has interested himself in this matter, with a quantity of dissolved gases obtained from the condensing water of his steam engine.

As to the spectrum, we have been indebted from the first to Mr. Crookes, and he has been good enough to-night to bring some tubes which he will operate, and which will show you at all events the light of the electric discharge in argon. I cannot show you the spectrum of argon, for unfortunately the amount of light from a vacuum tube is not sufficient for the projection of its spectrum. Under some circumstances the light is red, and under other circumstances it is blue. Of course when these lights are examined with the spectroscope—and they have been examined by Mr. Crookes with great care—the differences in the colour of the light translate themselves into different groups of spectrum lines. We have before us Mr. Crookes' map, showing

the two spectra upon a very large scale. The upper is the spectrum of the blue light; the lower is the spectrum of the red light; and it will be seen that they differ very greatly. Some lines are common to both; but a great many lines are seen only in the red, and others are seen only in the blue. It is astonishing to notice what trifling changes in the conditions of the discharge bring about such extensive alterations in the spectrum.

One question of great importance, upon which the spectrum throws light is, Is the argon derived by the oxygen method really the same as the argon derived by the magnesium method? By Mr. Crookes' kindness I have had an opportunity of examining the spectra of the two gases side by side, and such examination as I could make revealed no difference whatever in the two spectra, from which, I suppose, we may conclude either that the gases are absolutely the same, or, if they are not the same, that at any rate the ingredients by which they differ cannot be present in more than a small proportion in either of them.

My own observations upon the spectrum have been made principally at atmospheric pressure. In the ordinary process of sparking, the pressure is atmospheric: and, if we wish to look at the spectrum, we have nothing more to do than to include a jar in the circuit, and put a direct-vision prism to the eye. At my request, Prof. Schuster examined some tubes containing argon at atmospheric pressure prepared by the oxygen method, and I have here a diagram of a characteristic group. He also placed upon the sketch some of the lines of zinc, which were very convenient as directing one exactly where to look. (See Fig. 1.)

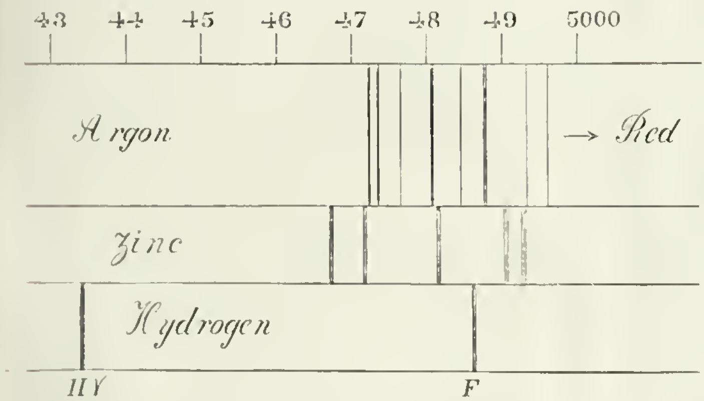

FIG. 1.

Within the last few days, Mr. Crookes has charged a radiometer with argon. When held in the light from the electric lamp, the vanes revolve rapidly. Argon is anomalous in many respects, but not, you see, in this.

Next, as to the density of argon. Prof. Ramsay has made numerous and careful observations upon the density of the gas prepared by the magnesium method, and he finds a density of about 19·9 as compared with hydrogen. Equally satisfactory observations upon the gas derived by the oxygen method have not yet been made, but there is no reason to suppose that the density is different, such numbers as 19·7 having been obtained.

One of the most interesting matters in connection with argon, however, is what is known as the ratio of the specific heats. I must not stay to elaborate the questions involved, but it will be known to many who hear me that the velocity of sound in a gas depends upon the ratio of two specific heats—the specific heat of the gas measured at constant pressure, and the specific heat measured at constant volume. If we know the density of a gas, and also the velocity of sound in it, we are in a position to infer this ratio of specific heats; and by means of this method, Prof. Ramsay has determined the ratio in the case of argon, arriving at the very remarkable result that the ratio of specific heats is represented by the number 1·65, approaching very closely to the theoretical limit, 1·67. The number 1·67 would indicate that the gas has no energy except energy of translation of its molecules. If there is any other energy than that, it would show itself by this number dropping below 1·67. Ordinary gases, oxygen, nitrogen, hydrogen, &c., do drop below, giving the number 1·4. Other gases drop lower still. If the ratio of specific heats is 1·65, practically 1·67, we may infer then that the whole energy of motion is translational; and from that it would seem to follow by arguments which, however, I must not stop to elaborate, that the gas must be of the kind called by chemists monatomic.

I had intended to say something of the operation of determining the ratio of specific heats, but time will not allow. The result is, no doubt, very awkward. Indeed I have seen some indications that the anomalous properties of argon are brought as a kind of accusation against us. But we had the very best intentions in the matter. The facts were too much for us; and all we can do now is to apologise for ourselves and for the gas. Several questions may be asked, upon which I should like to say a word or two, if you will allow me to detain you a little longer. The first question (I do not know whether I need ask it) is, Have we got hold of a new gas at all? I had thought that that might be passed over, but only this morning I read in a technical journal the suggestion that argon was our old friend nitrous oxide. Nitrous oxide has roughly the density of argon; but that, as far as I can see, is the only point of resemblance between them.

Well, supposing that there is a new gas, which I will not stop to discuss, because I think the spectrum alone would be enough to prove it, the next question that may be asked is, Is it in the atmosphere? This matter naturally engaged our earnest attention at an early stage of the inquiry. I will only indicate in a few words the arguments which seem to us to show that the answer must be in the affirmative.

In the first place, if argon be not in the atmosphere, the original discrepancy of densities which formed the starting point of the investigation remains unexplained, and the discovery of the new gas has been made upon a false clue. Passing over that, we have the evidence from the blank experiments, in which nitrogen originally derived from chemical sources is treated either with oxygen or with magnesium, exactly as atmospheric nitrogen is treated. If we use atmospheric nitrogen, we get a certain proportion of argon, about 1 per cent. If we treat chemical nitrogen in the same way, we get, I will not say absolutely nothing, but a mere fraction of what we should get had atmospheric nitrogen been the subject. You may ask, why do we get any fraction at all from chemical nitrogen? It is not difficult to explain the small residue, because in the manipulation of the gases large quantities of water are used; and, as I have already explained, water dissolves argon somewhat freely. In the processes of manipulation some of the argon will come out of solution, and it remains after all the nitrogen has been consumed.

Another wholly distinct argument is founded upon the method of diffusion introduced by Graham. Graham showed that if you pass gas along porous tubes you alter the composition, if the gas is a mixture. The lighter constituents go more readily through the pores than do the heavier ones. The experiment takes this form. A number of tobacco pipes—eight in the actual arrangement—are joined together in series with indiarubber junctions, and they are put in a space in which a vacuum can be made, so that the space outside the porous pipes is vacuous, or approximately so. Through the pipes ordinary air is led. One end may be regarded as open to the atmosphere. The other end is connected with an aspirator so arranged that the gas collected is only some 2 per cent of that which leaks through the porosities. The case is like that of an Australian river drying up almost to nothing in the course of its flow. Well, if we treat air in that way, collecting only the small residue which is less willing than the remainder to penetrate the porous walls, and then prepare "nitrogen" from it by removal of oxygen and moisture, we obtain a gas heavier than atmospheric nitrogen, a result which proves that the ordinary nitrogen of the atmosphere is not a single body, but is capable of being divided into parts by so simple an agent as the tobacco pipe.

If it be admitted that the gas is in the atmosphere, the further question arises as to its nature.

At this point I would wish to say a word of explanation. Neither in our original announcement at Oxford, nor at any time since, until January 31, did we utter a word suggesting that argon was an element; and it was only after the experiments upon the specific heats that we thought that we had sufficient to go upon in order to make any such suggestion in public. I will

not insist that that observation is absolutely conclusive. It is certainly strong evidence. But the subject is difficult, and one that has given rise to some difference of opinion among physicists. At any rate this property distinguishes argon very sharply from all the ordinary gases.

One question which occurred to us at the earliest stage of the inquiry, as soon as we knew that the density was not very different from 21, was the question of whether, possibly, argon could be a more condensed form of nitrogen, denoted chemically by the symbol N_3. There seem to be several difficulties in the way of this supposition. Would such a constitution be consistent with the ratio of specific heats (1·65)? That seems extremely doubtful. Another question is, Can the density be really as high as 21, the number required on the supposition of N_3? As to this matter, Prof. Ramsay has repeated his measurements of density, and he finds that he cannot get even so high as 20. To suppose that the density of argon is really 21, and that it appears to be 20 in consequence of nitrogen still mixed with it, would be to suppose a contamination with nitrogen out of all proportion to what is probable. It would mean some 14 per cent. of nitrogen, whereas it seems that from $1\frac{1}{2}$ to 2 per cent. is easily enough detected by the spectroscope. Another question that may be asked is, Would N_3 require so much cooling to condense it as argon requires?

There is one matter on which I would like to say a word—the question as to what N_3 would be like if we had it? There seems to be a great discrepancy of opinions. Some high authorities, among whom must be included, I see, the celebrated Mendeleef, consider that N_3 would be an exceptionally stable body; but most of the chemists with whom I have consulted are of opinion that N_3 would be explosive, or, at any rate, absolutely unstable. That is a question which may be left for the future to decide. We must not attempt to put these matters too positively. The balance of evidence still seems to be against the supposition that argon is N_3, but for my part I do not wish to dogmatise.

A few weeks ago we had an eloquent lecture from Prof. Rücker on the life and work of the illustrious Helmholtz. It will be known to many that during the last few months of his life Helmholtz lay prostrate in a semi-paralysed condition, forgetful of many things, but still retaining a keen interest in science. Some little while after his death we had a letter from his widow, in which she described how interested he had been in our preliminary announcement at Oxford upon this subject, and how he desired the account of it to be read to him over again. He added the remark, "I always thought that there must be something more in the atmosphere."

A SPECTROSCOPIC PROOF OF THE METEORIC CONSTITUTION OF SATURN'S RINGS.[1]

THE hypothesis that the rings of Saturn are composed of an immense multitude of comparatively small bodies, revolving around Saturn in circular orbits, has been firmly established since the publication of Maxwell's classical paper in 1850. The grounds on which the hypothesis is based are too well known to require special mention. All the observed phenomena of the rings are naturally and completely explained by it, and mathematical investigation shows that a solid or fluid ring could not exist under the circumstances in which the actual ring is placed.

The spectroscopic proof which Prof. Keeler has recently obtained of the meteoric constitution of the ring, is of interest because it is the first *direct* proof of the correctness of the accepted hypothesis, and because it illustrates in a very beautiful manner the truthfulness of Doppler's principle, and the value of the spectroscope as an instrument for the measurement of celestial motions.

Since the relative velocities of different parts of the ring would be essentially different under the two hypotheses of rigid structure and meteoric constitution, it is possible to distinguish between these hypotheses by measuring the motion of different parts of the ring in the line of sight. The only difficulty is to find a method so delicate that the very small differences of velocity in question may not be masked by instrumental errors. Success in visual observations of the spectrum is hardly to be expected.

After a number of attempts, Prof. Keeler obtained two fine photographs of the lower spectrum of Saturn on April 9 and 10 of the present year. The exposure in each case was two hours, and the image of the planet was kept very accurately central on the slit-plate. After the exposure the spectrum of the Moon was photographed on each side of the spectrum of Saturn, and nearly in contact with it. Each part of the lunar spectrum has a width of about one millimetre, which is also nearly the extreme width of the planetary spectrum. On both sides of the spectrum of the ball of the planet are the narrow spectra of the ansæ of the ring. The length of the spectrum from *b* to D is 23 millimetres.

These photographs not only show very clearly the relative displacement of the lines in the spectrum of the ring, due to the opposite motions of the ansæ, but exhibit another peculiarity, which is of special importance in connection with the subject of the present paper. The planetary lines are strongly inclined, in consequence of the rotation of the ball, but the lines in the spectra of the ansæ do not follow the direction of the lines in the central spectrum; they are nearly parallel to the lines of the comparison spectrum, and, in fact, as compared with the lines of the ball, have a slight tendency to incline in the opposite direction. Hence the outer ends of these lines are less displaced than the inner ends. Now it is evident that if the ring rotated as a whole, the velocity of the outer edge would exceed that of the inner edge, and the lines of the ansæ would be inclined in the same direction as those of the ball of the planet. If, on the other hand, the ring is an aggregation of satellites revolving around Saturn, the velocity would be greatest at the inner edge, and the inclination of lines in the spectra of the ansæ would be reversed. The photographs are therefore a direct proof of the approximate correctness of the latter supposition.

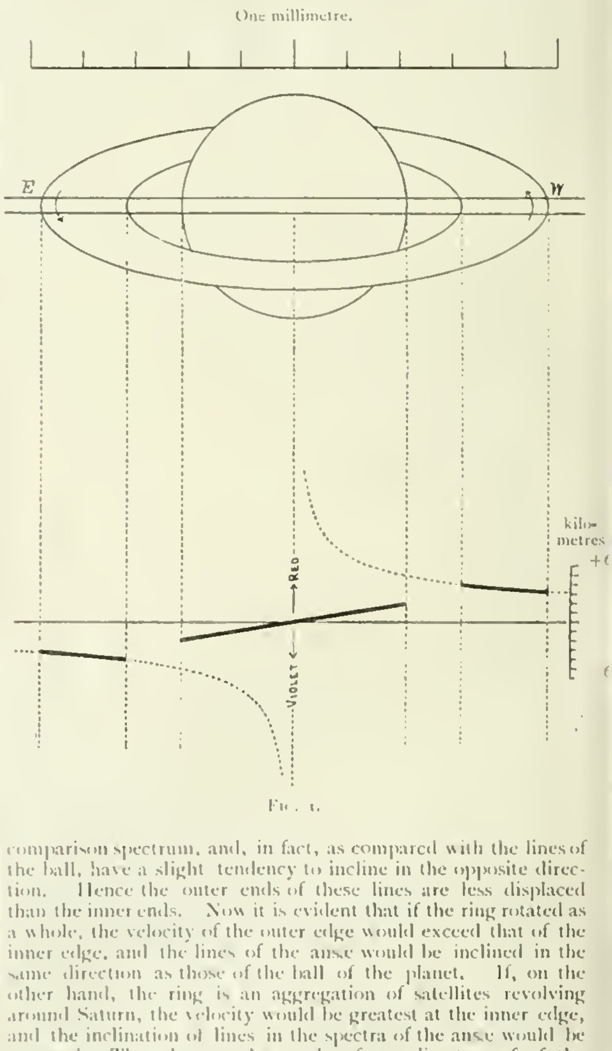

FIG. 1.

It is interesting to determine the form of a line in the spectrum of Saturn when the slit is in the major axis of the ring, on the assumption that the planet rotates as a solid body, and that the ring is a swarm of particles revolving in circular orbits according to Kepler's third law. At present the motion of the system as a whole is neglected. The upper part of Fig. 1 represents the image of Saturn on the slit of the spectroscope (the scale

[1] [illegible] Prof. James E. Keeler in the *Astrophysical Journal* [illegible]

above it applies to the instrument used at Allegheny), and the narrow horizontal line in the lower part of the figure represents an undisplaced line in the spectrum, or solar line.

By Doppler's principle, the displacement of any point on this line is proportional to the velocity in the line of sight. The inclination of the planetary line to the solar line can be expressed by a simple formula. It is also possible to determine the form of a line in the spectrum of the ring, regarded as a collection of satellites, by the application of Kepler's third law. With the computed motions of different parts of the system, the dotted curves in the figure were plotted. For the ordinates, however, twice the calculated values were taken, since the displacement of a line, due to motion in the line of sight, is doubled in the case of a body which shines by reflected and not by inherent light, provided (as in this case) the Sun and the Earth are in sensibly the same direction from the body. The planetary line is drawn to the same scale, and the heavy lines in the figure represent accurately the aspect of a line in the spectrum of Saturn, with the slit in the axis of the ring, as photographed with a spectroscope having about three times the dispersion of the instrument used by Prof. Keeler.

The width of slit used is also represented in the figure.

If the whole system has a motion in the line of sight, the lines in the figure will be displaced towards the top or the bottom, as the case may be, but their relative positions will not be altered.

It is evident that in making a photograph of this kind the image must be kept very accurately in the same position on the slit-plate, as otherwise the form of the lines shown in the figure would be lost by the superposition of points having different velocities. The second plate was made with special care, and as the air was steadier than on the first occasion, the definition is on the whole somewhat better than that of plate 1, although the difference is not great. On both plates the aspect of the spectrum is closely in accordance with that indicated by theory, and represented in the figure. The planetary lines are inclined from 3° to 4°, and the lines in the spectra of the ansæ have the appearance already described.

If the ring revolved as a whole, the displacement of lines in its spectrum would follow the same law as for a rotating sphere; that is, the lines would be straight and inclined, their direction passing through the origin. If the ring rotated in the period of its mean radius, a glance at the figure shows that the lines would practically be continuations of the planetary lines. Such an aspect of the lines as this would be recognisable on the photographs at a glance.

It will be seen from the foregoing considerations that the photographs prove not only that the velocity of the inner edge of Saturn's ring exceeds the velocity of the outer edge, but that, within the limits of error of the method, the relative velocities at different parts are such as to satisfy Kepler's third law.

Besides (1) the proof of the meteoric constitution of the rings, explained above, each line of the photographs gives (2) the period of rotation of the planet, (3) the mean period of the rings, (4) the motion of the whole system in the line of sight. Prof. Keeler has measured a number of lines on each plate, and compared the results with the computed values of the corresponding quantities.

The results for (2) and (3) from both photographs are:

(2) Velocity of limb = $10 \cdot 3 \pm 0 \cdot 4$ kilometres,
(3) Mean velocity of ring = $18 \cdot 0 \pm 0 \cdot 3$ kilometres;

the computed values being 10·29 and 18·78 kilometres respectively.

Prof. Keeler has not yet determined from his photographs the motion of the whole system in the line of sight.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. T. J. I. Bromwich, Scholar of St. John's College, is the Senior Wrangler of the year. There are thirty Wranglers, of whom St. John's furnishes ten, and Trinity six. One lady only is among the Wranglers, namely Miss N. A. L. Thring, of Newnham, who is placed twenty-third in the list.

The Tyson Medal for Astronomy is awarded to Mr. A. V. G. Campbell, of Trinity.

Sir Edward Maunde Thompson, K.C.B., has been appointed the first Sandars Reader in Bibliography for the year 1895-6.

The Board of Managers of the Arnold Gerstenberg Studentship give notice that a Studentship on this Foundation will be offered for competition in 1896. The competition will be open to men and women who have obtained honours in Part I. or Part II. of the Natural Sciences Tripos, and whose first term of residence was not earlier than the Michaelmas term of 1890. The Studentship will be awarded to the writer of the best essay on one of the six subjects printed below. The essays must be sent before October 1, 1896, to Dr. Sidgwick, Newnham College, Cambridge. The Studentship will be of the value of nearly £90. It will be tenable for one year only, but subject to no conditions of tenure.

Subjects:—"A statement of the physicist's 'working conceptions' of Matter and Motion, together with a discussion of the philosophical questions to which they give rise." "A criticism of the diverse views that have prevailed from the time of Newton onwards as to the conceivability or otherwise of *Actio in distans*." "A critical examination of the doctrines of J. S. Mill concerning the ground of Induction and the Methods of Inductive Inquiry." "The limits and relations of mechanical and teleological explanations of natural phenomena." "A brief historical account and a critical examination of the views which make the phenomena of life dependent on the existence of a special vital principle." "Natural Selection considered as a special example of the general principle of Evolution."

WITH the view of encouraging University Extension students to take up systematic courses of study, the Local Examinations and Lectures Syndics have remodelled their scheme of Local Lectures Certificates, and have made several other changes of importance. The certificates are now arranged so as to form successive steps in a ladder of continuous work, beginning with the Terminal Certificate for one term's work passing through the Sessional Certificate for a year's work to the Vice-Chancellor's Certificate of Systematic Study for four years' work. There is also an Affiliation Certificate obtainable only at centres affiliated to the University. This certificate is accepted by the Education Department as qualifying a person to be recognised as an assistant teacher. This system is thus adapted to the needs of persons who merely desire a general acquaintance with the subjects taught, as well as to students who are anxious to make a more thorough study of them.

THE Technical Education Board of the London County Council will proceed in July next to award five of its valuable Senior County Scholarships. These scholarships, which are reserved as a rule for young men and women under nineteen years of age, are intended to enable promising and deserving students, who would otherwise be unable to afford the expense, to go through a three years' course at a University or at a Technical Institute of University rank. They are limited to those candidates whose parents are in receipt of not more than £400 a year. The scholarships not only give free tuition, but also a money payment of £60 during each of the years that the scholarship is tenable. They are primarily intended to encourage the pursuit of some branch of science, art, or technology, but they may also be awarded for the promotion of studies in modern languages or other branches of education. In making the award, the Board takes mainly into account the record of each candidate's past career and distinctions, and the evidence as to ability, industry, and good character which the candidate is able to supply. At the same time it reserves the right to apply any examination test that it may think fit. Full particulars may be obtained from the Secretary of the Board, at 13 Spring Gardens, S.W. Candidates should send in their names not later than June 29.

THE summer assembly of the National Home-Reading Union will be held at Leamington Spa, from Saturday, June 29, to Monday, July 8. Lectures will be given by Major Leonard Darwin, M.P., on "The National and International Advantages of the Study of Geography"; Sir Robert Ball, on "Comets"; Mr. H. Yule Oldham, on "The Discovery of America"; Mr. J. E. Marr on "The Geology of the District"; Mr. G. F. Scott Elliot, on "Interesting Problems in Botany, suggested by the Flora of the District." There will also be a conference on "The Wider Education," at which the chair will be taken by Dr. Hill, Master of Downing College, Cambridge. Addresses will be given by Miss Mondy, Dr. R. D. Roberts, a representative of the Oxford Delegacy for University Extension, Mr. T.

C. Horsfall, Mr. J. E. Flower (Secretary Recreative Evening Schools Association), and other speakers. Excursions will be made to a number of places in the district, and Profs. W. Ridgeway and T. McKenny Hughes, Mr. J. G. Marr, Mr. Scott Elliot, and others, will accompany the excursions for the purpose of explaining the archæology, geology, and botany of the places visited.

Mr. C. J. FORTH, Mathematical Master at Bolton Grammar School, has been appointed Lecturer in Mathematics at the Plymouth Technical Schools.

THE textile department of the Yorkshire College at Leeds has just been added to by the opening of a museum which is to contain a complete collection of woven samples and models of weaving machinery. The building has cost the Clothworkers' Company £3000, and they will, to the extent of £1200, defray the cost of equipping the museum. The opening ceremony was performed by Mr. Sidney Wilson, Master of the Clothworkers, assisted by Mr. J. E. Horne, his senior warden, and other members and officials. Twenty years ago the Clothworkers established the textile department of the college at the cost of £34,000, and they make an annual grant to it of £2500.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, May 16.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read:—Kjeldahl's method for the determination of nitrogen, by B. Dyer. The author describes an exhaustive series of experiments made with the various modifications of Kjeldahl's process in order to ascertain their applicability to organic nitrogen compounds of different types.—Note on liquation in crystalline standard gold, by T. K. Rose.—Preparation of the active lactic acids, and the rotation of their metallic salts in solution, by T. Purdie and J. W. Walker. The optical activity of the metallic lactates in aqueous solution is in the opposite sense to that of the active acid from which they are derived; cryoscopic determinations made with the lithium and strontium lactates show that the racemic form is resolved into the two active ones in aqueous solution.—Derivatives of succinyl and phthalyl dithiocarbimides, by A. E. Dixon and R. E. Doran. On heating succinyl or phthalyl chlorides with lead thiocyanate and dry benzene, succinyl or phthalyl dithiocarbimide, respectively, is formed; a number of derivatives of these two substances are described.—The action of nitrous acid on dibromaniline, $C_6H_3BrBr.NH_2$ = 1 : 4 : 2, by R. Meldola and E. R. Andrews. The authors were unsuccessful in preparing a diazoxide from dibromaniline under the conditions which yield these compounds in the naphthalene series; in the present case a diazoamido-derivative, $C_6H_3Br_2.N_2.NH.C_6H_3Br_2$, was obtained.—A new modification of benzilosazone, by H. Ingle and H. H. Mann. The unstable α-benzilosazone, corresponding to the known β isomeride, is obtained, together with dibenzaldiphenylhydrotetrazone by the action of iodine on a mixture of benzalphenylhydrazone and sodium ethoxide.—Affinity of weak bases, by J. Walker and E. Aston.—Substitution derivatives of urea and thiourea, by A. E. Dixon. The properties of a number of substituted ureas are described.—Note on some reactions of ammonium salts, by W. R. E. Hodgkinson and N. E. Bellairs. Fused ammonium nitrate and sulphate are readily attacked by many metals with evolution of ammonia; other products, such as hydrogen and sulphites, also result in certain cases.

Zoological Society, May 21.—Lieut.-Colonel H. H. Godwin-Austen, F.R.S., Vice-President, in the chair.—Dr. R. Bowdler Sharpe gave an account of the ornithological collection made by Dr. Donaldson Smith during his recent expedition into Somaliland and Gallaland. The present series contained about 500 specimens, which were referred to 182 species. Of these twelve were considered to be new to science.—Mr. G. A. Boulenger, F.R.S., read a synopsis of the genera and species of apodal batrachians, and gave a description of a new genus and species proposed to be called *Bdellophis vittatus*.—Lieut.-Colonel H. H. Godwin-Austen, F.R.S., read a list of the land-molluscs of the Andaman and Nicobar groups of islands in the Bay of Bengal, and gave descriptions of some new species, together with a complete account of the distribution of all the species in the various islands of these two groups.—A communication was read from Dr. J. Anderson, F.R.S., containing the description of a new species of hedgehog from Somaliland, which he proposed to name *Erinaceus sclateri*.—A communication from Mr. R. Lydekker contained notes on the structure and habits of the sea-otter (*Latax lutris*).—A communication was read from Dr. B. C. A. Windle containing remarks on some double malformations observed amongst fishes.—Mr. F. E. Beddard, F.R.S., read a paper on the visceral and muscular anatomy of *Cryptoprocta*, dealing chiefly with the brain, alimentary canal, and muscles of this carnivore.

Geological Society, May 22.—Dr. Henry Woodward, F.R.S., President, in the chair.—On a human skull and limb-bones found in the palæolithic terrace-gravels at Galley Hill, Kent, by E. T. Newton, F.R.S. A human skull with lower jaw and parts of the limb-bones were obtained by Mr. R. Elliott from the high-terrace gravels at Galley Hill, in which numerous palæolithic implements have been found. The skull is extremely long and narrow, its breadth-index being about 64, it is hyperdolichocephalic; it is likewise much depressed, having a height-index of about 67. The small extent of the cranium in both height and width shows that it has undergone little or no post-mortem compression, although it has become somewhat twisted in drying. The supraciliary ridges are large, the forehead somewhat receding, the probole prominent, and the occiput flattened below. All the chief sutures are obliterated. Three lower molars and two premolars are in place and are well worn, the three molars being as nearly as possible equal in size. The limb-bones indicate an individual about 5 ft. 1 in. in height. These remains were compared with the fossil human relics which have been found in Britain and on the continent of Europe, as well as with the dolichocephalic races now living, and their relations to the "Spy," "River-bed," "Long-barrow," "Eskimo," and other types were pointed out. The gravels, in which these human bones were found, overlie the chalk at a height of about 90 feet above the Thames, and are about 10 feet thick. They form part of the high-terrace gravels extending from Dartford Heath to Northfleet, and their palæolithic age is shown by the numerous implements which have been found in them, as well as by the mammalian remains which have been met with in similar beds near by, although not at Galley Hill. The human bones were seen *in situ* by Mr. R. Elliott and Mr. Matthew Heys, both of whom speak positively as to the undisturbed condition of the 8 feet of gravel which overlay the bones when discovered.—Geological notes of a journey round the coast of Norway and into Northern Russia, by G. S. Boulger. The author accompanied the Jackson-Harmsworth Polar Expedition as far as Archangel, and returned by way of the River Dvina. His observations relate mainly to four points: the origin of the foliation of the Norwegian gneiss; the question of raised beaches on the north-western coast of Norway; the boulders and boulder-formation of Northern Russia; and the Trias of the Dvina valley. Between Christiansund and Tromsö the author was struck with the wide-sweeping folds of the foliation-planes of the gneissose rocks, which appeared to him more readily explicable on a theory of dynamo-metamorphism of rocks originally in part igneous, than by any process of diagenesis. He noted that the terraces observed in the transverse fjords would be perfectly explained by the formation of ice-dammed lakes, though the terraces of the Gulf of Onega seemed less dubious raised beaches than those of the north west of Norway. He confirmed the views of previous writers that many of the boulders of the boulder-formation of Northern Russia were of Scandinavian origin. The beds on the Dvina consist of sands and loams, often coloured red, with bands of alabaster and anhydrite. The strata are horizontal or inclined at a low angle. North of Ustyug Veliki the strata are marked as Permian on the Russian maps, and those to the south as Trias, but the author saw no perceptible break in the succession.—On some Foraminifera of Rhætic Age, from Wedmore in Somerset, by Frederick Chapman. The author has examined six samples of clays and limestones collected from a quarry south-east of the village of Wedmore, which has yielded Megalosaurian remains. The microscopical details of the various clay-washings were given, and the great abundance of some forms of the acervuline foraminifer *Stacheia* was noticed. In a comparison made with the foraminiferal fauna of the older and younger rocks respectively, the Rhætic fauna shows marked affinities with both the Upper Palæozoic and the Liassic facies. Twenty-six species of foraminifera, chiefly of arenaceous types, were described, nine of which are new forms.

PARIS.

Academy of Sciences, June 4.—M. Lœwy in the chair. Notice on the works of M. Neumann, by M. J. Bertrand. Franz Neumann, correspondent of the Geometry Section, died at Königsberg on May 23 last. He will be chiefly remembered by his great memoir "On the theory of undulations," in which he considers luminous vibrations as occurring in the plane of polarisation. His great mathematical ability was especially shown by the general formulæ in which he expressed the results of Faraday's discoveries and Lenz's rules.—Volume of salts in their aqueous solutions, by M. Lecoq de Boisbaudran. The author compares the dilatometer and pyknometer methods, and describes a special form of dilatometer used in this work.—A contribution to the study of the acetylcyanacetic esters of the general formula,

$$C_nH_{2n+1}.CO.CH\left\langle\begin{matrix}CN\\ CO_2R\end{matrix}\right.$$

or

$$C_nH_{2n+1}.CH:COH.CH\begin{matrix}CN\\ \\ CO_2R\end{matrix},$$

by M. A. Haller.—A projected Swedish exploration of Tierra del Fuego, by M. Daubree. The Swedish Government is about to send out an expedition of three persons to explore the unknown parts of Tierra del Fuego, and the Argentine Government will assist by conveying the members of the exploring party to their destination and finding attendants. MM. Nordenskiöld, Dusen, and Ohlin will arrive at Buenos Ayres in September, and hope, during the Antarctic summer, to explore those parts of the island unvisited by the French expedition of 1882-1883. They aim particularly at gathering material for a comparison of the southern island with Northern Europe; for instance, the quaternary rocks of Tierra del Fuego will be compared with rocks of the same age in the boreal continents.—Report on the project of a balloon expedition to the Polar regions, by M. J. A. Andrée (Committee: MM. Faye, Daubree, Blanchard). It is reported that the conditions for the success of such an expedition have been fully considered, the funds necessary have been raised, and the expedition will set out from Spitzbergen in July of the coming year. The conditions formulated by M. Andrée are: (1) The balloon must have an ascensional power sufficient to carry three persons, all the necessary instruments, food for four months, arms, a boat transformable into a sledge, and the ballast, in all about 3000 kilograms. (2) The balloon must have the quality of impermeability to such an extent that it can remain thirty days in the air. (3) It must be to a certain extent dirigable.—Memoirs presented: By M. A. Lucas, on the centrifugal and centripetal forces and on a new value of *g*; by M. Bonoal, an alcoholimeter allowing the simultaneous estimation of alcohol and extract in wines.—Observations of Charlois' planet BX, made with the Coudé equatorial at Algiers Observatory, by MM. Rambaud and Sy.—On the movement of a plane figure in its plane, by M. A. Pellet.—On a category of groups of substitutions associated with groups of which the order equals the degree, by M. R. Levavasseur.—On the density of helium (a letter from M. Clève to M. Berthelot). (See Notes.)—On the reduction of nitrous oxide by metals in presence of water, by MM. Paul Sabatier and J. B. Senderens. The results fully confirm those formerly obtained. Dissolved nitrous oxide is reduced to the state of nitrogen by magnesium, zinc, iron, and even cadmium, with the simultaneous formation of a little ammonia.—Heat of formation of sodium acetylide, by M. de Forcrand.—On phthalyl chloride and phthalide, by M. Paul Rivals.—Conductibility of some β-ketonic esters, by M. J. Guinchant. The sodium salts of the *cyanomethinic* acids behave quite normally with regard to conductibility. These acids, as well as acetylacetone, obey Ostwald's law (K = const.) as far as can be expected with compounds containing an acid group and an ether function. Their chemical affinity deduced from thermochemical data agrees well with that obtained from their conductibilities. The values of K for homologous acids diminish as the molecular weight increases.—Estimation of volatile acids in wines, by M. E. Burcker.—Considerations on the chemical phenomena of ossification, by M. C. Chabrie.—On the flora of the coal deposits of Asia Minor, and the presence in this flora of the genus *Phyllotheca*, by M. R. Zeiller.—On the chlorosis of American vines and its treatment by sulphuric acid, by MM. Gastine and Degrully. The authors find treatment by ferrous sulphate and by sulphuric acid to yield identical results; it is concluded that the sulphuric acid is the active agent in overcoming chlorosis.—*Oidium albicans*, a general pathogenic agent. Pathogeny of morbid disorders, by MM. Charrin and Ostrowsky. In conclusion, the study of the general disease which determines inoculation by *Oidium albicans* reveals a series of processes peculiar to this fungus. Comparing these processes with those due to bacteria, some analogies, but more differences, are observed.

BERLIN.

Physiological Society, May 3.—Prof. H. Munk, President, in the chair.—After the President had dwelt on the loss physiology had suffered by the death of Prof. Ludwig, Prof. I. Munk spoke on Kjeldahl's method for determining nitrogen in organic substances as compared with Dumas' method. The former has largely supplanted the latter owing to the greater ease with which it may be carried out, but some chemists have found it less accurate than that of Dumas, notably when applied to casein. The speaker had recently repeated the analysis, and found the above statement confirmed as long as he used oxide of copper in Kjeldahl's process. But when he used oxide of mercury (Wilfarth) or potassium bichromate (Krüger), the two methods gave identical results for the nitrogen. He had also found Kjeldahl's method applicable to nitrogenous compounds with closed rings, such as pyridin, chinolin, &c. Prof. Gad developed Fick's hypothesis as to the two-fold nature of the chemical processes taking place in a contracting muscle, a hypothesis to which he gave his support on the basis of his experiments made together with Heymans (see NATURE, vol. xl. p. 288), on the influence of temperature on muscular contraction. He described several experiments on the production of heat in muscles contracting isotonically and isometrically, which can be most readily explained on the basis of Fick's hypothesis of two mutually interfering chemical processes.

May 17.—Prof. H. Munk, President, in the chair.—Dr. W. Cowl spoke on the action of diaphragms in microscopes, aod explained a general improvement he had obtained by applying an iris-diaphragm to the ocular, capable of regulation from the outside.—Dr. Thierfelder gave an account of experiments made with Dr. Nutan on guinea-pigs.

Physical Society, May 10.—Prof. von Bezold, President, in the chair. After election of officers, Prof. Konig spoke on experiments made in conjunction with Dr. Rubens on the distribution of energy in the spectrum of a triplex burner. The methods employed made it possible to measure the energy by means of a bolometer between W.L. 800 μ to W.L. 420 μ, and at the same time to measure the intensity of the light at the same part of the spectrum by means of a Lummer photometer. He dealt in great detail with the correction which is necessary on account of the fact that diffused light acts on the bolometer in addition to that of each giveo wave-length. The curve of energy thus obtained was so steep that it could only be recorded by logarithms; the energy of the extreme red was more than a thousand times as great as that of the blue. By comparing the relative intensities of the rays of a normal amylacetate flame with that of the above burner, the distribution of energy in the amylacetate flame was deduced by calculation, and in this case also the curve was very steep; the energy of the red end being 300 times that of the blue. The curve for the spectrum of the cloudless sky ascended from the red towards the blue end, whereas it was nearly horizontal for the light from a cloud. Prof. Neesen exhibited two automatic mercurial air-pumps.

May 24.—Prof. du Bois Reymond, President, in the chair.—Prof. Neesen described an automatic mercurial valve added to his automatic pumps. Prof. von Bezold spoke on a theory of terrestrial magnetism, based on the construction of the isonomals of terrestrial magnetic potentials. He explained the methods by which he had calculated the isonomals, and discussed the results observable on a chart of the same for the year 1880. The mean values of magnetic potential are simple functions of geographical latitude, and the isonomals have both their poles in the southern hemisphere. The determination of the potential and the construction of the lines of equilibrium is far simpler by Prof. von Bezold's method than by the employment of Gauss's formulæ, and will make it possible to attack a whole series of important problems concerning terrestrial magnetism. As soon as isonomal charts have been constructed for different periods it will be possible to draw conclusions as to the causes of magnetic disturbances.

NEW SOUTH WALES.

Linnean Society, April 24.—The President, Mr. Henry Deane, in the chair.—Description of a fly-catcher, presumably new, by C. W. de Vis. The name *Arses borealis* was proposed for a fly-catcher from Cape York, with the lower surface entirely white in the male, ochreous in a band on the lower throat in the female, and with white lores in both sexes.—On the specific identity of the Peripatus, hitherto supposed to be *P. leuckarti*, Sanger, by J. J. Fletcher. It was shown by a translation of Sanger's paper (in Russian) descriptive of the Australian Peripatus, that *P. insignis*, Dendy, is a synonym of *P. leuckarti*. Various considerations point to the following classification of Australian Peripatus: *Peripatus leuckarti*, Sang. Australian Peripatus with 14 or 15 pairs of walking legs; without or with an accessory tooth at the base of the fang of the outer jaw blade, or with several (three in one case, indications of even more in another). Males with a pair of (accessory genital) pores between the genital papilla and the anus; with a white tubercle on each leg of the first pair only, or of the last pair only, or of all or only some of the pairs with the exception of the first. (1) *P. leuckarti*, Sang., var. *typica* (*P. leuckarti*, Sang.: *P. insignis*, Dendy). With 14 pairs of walking legs; no accessory tooth; New South Wales, Victoria, Tasmania. (2) *P. leuckarti*, Sang., var. *occidentalis*. With 15 pairs of walking legs; no accessory tooth; West Australia (Mr. A. M. Lea). (3) *P. leuckarti*, Sang., var. *orientalis* (*P. leuckarti*, Sang.) With 15 pairs of walking legs; with one or more accessory teeth; viviparous; Queensland, New South Wales. (4) The Victorian Peripatus described by Dr. Dendy as *P. oviparus*. Victoria and Tasmania (probably—for a specimen in the Macleay Museum).—Description of *Peripatus oviparus*, by Dr. A. Dendy. In the light of knowledge gained from the translation of Sanger's description of *P. leuckarti*, already referred to, and the consequent necessary revision of the nomenclature at present in use, the author dealt at length with the larger Victorian Peripatus, which he proposed to call *P. oviparus*.—Notes on the sub-family *Brachyscelinae*, with descriptions of new species, by W. W. Froggatt. This paper comprised notes upon the classification and systematic position of the gall-making Coccids, some corrections in the earlier descriptions of *Brachyscelis Thorntoni*, together with descriptions of three new species proposed to be called *B. dipsaciformis*, *B. sessilis*, and *B. [illegible]iformis*.—On a Fiddler Ray (*Trygonorhina fasciata*) with abnormal pectoral fins, by J. P. Hill. The specimen observed, a young male 20·0 cm. long, presented a striking appearance by reason of the anterior portion of each pectoral fin being separated from the head by a wide and deep notch. The significance of the abnormality was discussed at some length.

AMSTERDAM.

Royal Academy of Sciences, April 18.—Prof. Van de Sande Bakhuyzen in the chair.—Prof. MacGillavry gave a sketch of two methods employed by him to detect the adulteration of butter with less than one per cent. of oleo-margarine or with oils.—Prof. Pekelharing read a paper on the objections raised against his view as to the nature of the fibrine ferment, viz. that it is a compound of nucleoproteid and lime, more particularly on the objections brought forward by Halliburton, who, by his important and extensive investigations, has contributed so much to our knowledge in this department. The author had found (1) that artificial fibrine ferment, prepared by treating nucleoproteid first with lime-water and then with carbonic acid, became only partly [illegible] by being kept under alcohol for a long time, whereas [illegible] treated in the same manner as Schmidt's ferment, it yielded a [illegible]ful fibrino-plastic solution; (2) that magnesium sulphate [illegible] liquid, not for want of nucleoproteid, but because it did not contain enough calcium salts. The magnesium [illegible] prevented the combination of nucleoproteid and lime; but when the combination had once been brought about, $MgSO_4$ [illegible] the coagulation in a much smaller degree. Magnesium [illegible] was coagulated by artificial fibrine just as well as [illegible] from blood serum; (3) that intravenous injection of [illegible] ferment had the same consequence [illegible] of nucleoproteid, viz. Wool[illegible] coagulation of the [illegible] from the vessels. On the other hand, it [illegible] of fibrine ferment, prepared by [illegible] of a rabbit, the animal [illegible]. Prof. Schoute proved that the [illegible] of the regular system in a space of n dimensions is $2^n - 1$.—Prof. Kamerlingh Onnes communicated the results of investigations by Mr. A. Lebret in the Leyden laboratory: (1) compensation method of the observation of Hall's effect; (2) on the dissymmetry of Hall's effect in bismuth when the directions of the magnetic field are opposite to each other. In every plate there are two perpendicular directions of great importance. The primary electrodes being attached in accordance with these directions, there is no dissymmetry. When they are attached in a direction making an angle α with one of them, the Hall effect is given by $H \pm \frac{1}{2}(K_1 - K_2) \sin 2\alpha$. It is explained by a difference between the variations of resistance through magnetisation K_1 and K_2 in two perpendicular directions.

BOOKS AND SERIALS RECEIVED.

BOOKS.—Dairy Bacteriology: Dr. E. von Freudenreich, translated by Prof. J. R. A. Davis (Methuen).—Petrology for Students: A. Harker (Cambridge University Press).—A Text-Book of Zoogeography: F. E. Beddard (Cambridge University Press).—Hydrodynamics: Prof. H. Lamb (Cambridge University Press).—Museums Association. Report of Proceedings, &c., at the Fifth Annual General Meeting, held in Dublin, June 26 to 29, 1894 (Sheffield).—The Horticulturist's Rule-Book: L. H. Bailey, 3rd edition (Macmillan).—Agriculture: R. H. Wallace (Chambers).—Off the Mill: Bishop G. F. Browne (Smith, Elder).—Bibliotheca Geographica, Band 1 (Berlin, Kühl).

SERIALS.—Journal of the Anthropological Institute, May (K. Paul).—Bulletin of the American Mathematical Society, May (New York, Macmillan).—Proceedings of the Physical Society of London, June (Taylor).—Report of the Marlborough College Natural History Society, 1894 (Marlborough).—Journal of the Chemical Society, June (Gurney).—Geological Magazine, June (Dulau).—Phycological Memoirs, Part 3 (Dulau).—Ethnographische Beiträge zur Kenntnis des Karolinen Archipels, 3 Heft (Leiden, Trap).—Natural History of Plants, Part 13; Kerner and Oliver (Blackie).—American Journal of Science, June (New Haven).—Materials for a Flora of the Malayan Peninsula, No. 7: Dr. G. King (Calcutta).—Journal of the Asiatic Society of Bengal, Vol. lxiii. Part 2, No. 4 (Calcutta).—Ditto Vol. lxiv. Part 2, No. 1 (Calcutta).—Science Progress, June (Scientific Press, Ltd.).—Strand Magazine, June (Newnes).—Picture Magazine, June (Newnes).—Engineering Magazine, June (Tucker).

THE ATOMIC THEORY AND ITS AUTHOR.

John Dalton and the Rise of Modern Chemistry. By Sir Henry E. Roscoe, D.C.L., LL.D., F.R.S. Century Science Series. Pp. 212. (London: Cassell and Company, Ltd., 1895.)

WE have read through this little book from beginning to end with a great deal of pleasure. It tells the story of a life which has already been told more than once, but it tells it in a pleasant style, while at the same time it is fairly complete and, what is equally important in these days, not too long.

John Dalton was born at Eaglesfield, near Cockermouth in Cumberland, in 1766, about September 6; but as no register containing a record of his birth has been found, the exact date is not known. John is supposed to have been the second son of his parents, Joseph and Deborah Dalton, but, for the same reason, this statement cannot now be verified. According to his own account he attended the village schools in the neighbourhood, and was fortunate in attracting the notice of Mr. Elihu Robinson, a Quaker like his parents; but while Joseph Dalton was but a humble hand-loom weaver, Robinson was a man of independent means and considerable scientific ability. Under the influence of Mr. Robinson, John made such progress, especially in mathematics, that at the age of twelve he set up school teaching on his own account. When he was about fifteen he left his native place, in order to join his elder brother Jonathan in the conduct of a school at Kendal. Four years later, in 1785, George Bewley, the proprietor of the school retired from the management, and John became his brother's partner. A quaint card, reproduced photographically in the book, announced to their friends and the public that youth would be "carefully instructed in English, Latin, Greek, and French, also writing, arithmetic, merchants' accompts, and the mathematics."

All this time John was diligently occupied in self-improvement. His active mind, however, could not be contented with mere acquisition of knowledge, and we find that his first attempts at scientific investigations were made here. Meteorological observations occupied him in the first instance, and the requisite barometers and thermometers were made with his own hands. This was the beginning of the long series of daily observations which were continued without a break until the evening before his death in 1844.

In 1793 Dalton left Kendal for Manchester, having undertaken for the modest stipend of £80 a year to teach mathematics, mechanics, geometry, book-keeping, natural philosophy, and chemistry, and we are told that in 1794 he had twenty-four students in these subjects. In this position of college tutor Dalton remained six years, and then resigned his post in order to obtain time for his researches, supporting himself by private tuition. When he left the college, he lived first in a house in Faulkner Street, then with John Cockbain, a member of the Society of Friends; but, after a time, joined the family of the Rev. William Johns, with whom he remained nearly thirty years. It was here that his most important original work in physics and chemistry was accomplished, here he brought out his system of chemical philosophy, and here he attained to that celebrity which brought him honours from abroad, as well as the friendship of the most distinguished of his own countrymen.

To the pages of the book we must refer our readers for many of the details of Dalton's subsequent career: how he delivered courses of lectures in Edinburgh and Glasgow (1807), and twice at the Royal Institution in Albemarle Street (1803–4 and 1809–10); how he was made a corresponding member of the French Academy of Sciences (1816), and a Fellow of the Royal Society (1822); how he visited Paris (1822), and subsequently, after the death of Davy, was elected a Foreign Associate of the Academy (1830); how he received honorary degrees from many universities, among the rest, from Oxford (1832); and, finally, was assigned a pension out of the funds of the Civil List by King William the Fourth.

Dalton died on July 27, 1844. Since 1837, when he had a paralytic stroke, his vigour had very seriously declined; and of this decline it is obvious that he was conscious. Old people are usually parsimonious, especially if in their younger days they have been obliged to practise economy. Dalton was no exception to this, and an amusing account, which will not bear condensation, is given of a transaction of his with Dr. Lyon Playfair, in January 1844, only a few months before his death.

Dalton seems to have been a great smoker. In a letter quoted on p. 166, he says (January 10, 1804):

"I was introduced to Mr. Davy, who has rooms adjoining mine in the Royal Institution. He is a very agreeable and intelligent young man, and we have interesting conversations in an evening. The principal failing in his character is that he does not smoke."

Wrapt as he was from early youth in his scientific and philosophical pursuits, it is perhaps not surprising that he should have declared that his head was "too full of triangles, chemical processes, and electrical experiments, &c., to think much of marriage." Nevertheless, it appears that the Quaker philosopher had at least one or two affairs of the heart, and even when past the age of giddy youth he seems to have been accessible to the charm of female beauty: for in a letter in which he describes "the belles of New Bond Street," he admits that he is "more taken up with their faces than their dresses," and ends with the remark, "I do not know how it happens, but I fancy pretty women look well anyhow."

Every one has heard of Dalton's peculiarities of vision. It seems remarkable that he should have grown to manhood without becoming aware of his defect, but it appears that it was not till about the age of six-and-twenty that he found out that his notions of green and red were different from those of other people. This evidently caused him at first a good deal of perplexity, and brought down a certain amount of "chaff," for he writes to his old friend Elihu Robinson, that "the young women tell me they will never suffer me to go into the gallery of the meeting-house with a *green* coat; and I tell them I have no objection to their going in with me in a *crimson* (that is, dark drab) gown." Dalton had a notion that his defect of vision was due to the existence of a coloured medium in one of the humours of the eye. It is almost needless to

say that this was a mistake, and that the fact has now long been recognised that many persons are unable to distinguish red and green, though the true physiological explanation is still unknown.

We must now turn to a brief consideration of the chief subject of Dalton's scientific investigations. In connection with the history of the evolution of the atomic theory, Sir Henry Roscoe has been so fortunate as to make an interesting discovery. Among the "Dalton Papers" in the possession of the Manchester Literary and Philosophical Society, he has found the manuscript notes prepared by Dalton for the course of lectures delivered at the Royal Institution in the winter of 1809–10. In these notes he gives an account of the train of thought which led him to adopt the atomic hypothesis for the explanation of chemical phenomena. Contrary to the commonly received account, which appears to have originated with a statement by Dr. Thomas Thomson in his "History of Chemistry," the atomic theory did not first occur to him during his investigation of olefiant gas and carburetted hydrogen gas. From the newly-discovered manuscript it appears that Dalton's atomistic ideas arose in the course of his study of the atmosphere, and in speculating as to how a mixture of two or more elastic fluids could constitute a homogeneous mass. A reader of his "Chemical Philosophy" would perceive how thoroughly he was imbued with the Newtonian doctrine of particles, and in Henry's "Life" this is clearly pointed out.

By whatever process Dalton arrived at the adoption of the atomic hypothesis, it is certain that his great merit consisted in the application of a commonly accepted (see "Chemical Philosophy," part i. p. 141), but vaguely conceived, notion to the explanation of chemical phenomena. It was "for the development of the chemical theory of definite proportions, usually called the 'Atomic Theory,'" more especially, that he received the first awarded Royal Medal in 1826. This is the point upon which emphasis was particularly placed by the president, Sir Humphry Davy, in presenting the medal.

In the course of reading this little book we have met with only one passage which seems to require correction. The statement (p. 153) that Dalton's "great achievement was that he was the first to introduce the idea of quantity into chemistry" is not only erroneous but is inconsistent with the writer's own text, which on p. 161 contains a reference to the names of Wenzel and Richter.

We shall look forward with pleasure to the other volumes of the series. W. A. T.

HYDRAULIC AND OTHER POWERS.

Hydraulic Motors, Turbines, and Pressure Engines. By G. R. Bodmer, A.M.Inst.C.E. Pp. 540. (London: Whittaker and Co., and George Bell and Sons, 1895.)

Motive Powers and their Practical Selection. By Reginald Bolton, A.M.Inst.C.E. Pp. 250. (London and New York: Longmans, Green, and Co., 1895.)

THE first of these works is a second and enlarged edition of an excellent treatise on a subject seldom dealt with in English text books. The question of the application of water power to useful purposes is becoming more and more of importance, and the study of the design and construction of the necessary machinery naturally follows. Continental engineers are in advance of us in this matter, they having long studied the problem successfully. This difference, however, is rapidly disappearing, and will be greatly assisted by the issue of this work.

The author has consulted to a greater or less extent many works and publications, and appears to have brought together much valuable information; this, combined with his own experience, makes the work an important one. Historical matter has been purposely avoided, as well as descriptions of obsolete forms of motors. The author rather jocularly observes in his preface that he is sure to be criticised, one way or the other, as to the use of mathematics in his work. On the question of the free use of mathematical methods we are entirely of his opinion, viz. that formulæ afford the readiest means of accurately stating facts which in the simplest cases can only be verbally defined in elaborate phraseology. The description of the Niagara Falls installation is concise and to the point. This installation is designed for utilising 10,200 cubic feet of water per second, with an available head of 140 feet, which is equivalent, with an assumed efficiency of turbine of 75 per cent. to about 120,000 horse power. The turbines were designed by Messrs. Faesch and Piccard, of Geneva, and made by the I.P. Morris Company of Philadelphia; each of these wheels is to develop 5000-horse power, with a mean head of 136 feet. Other interesting descriptions of recent installations are added, but we miss an account of the Worcester Electric Lighting Station. This is to be regretted, because the installation is an example of a considerable application of water-power under somewhat adverse conditions. The ground covered in this book, both theoretical and practical, is of considerable extent. The author handles the subject in a sensible manner, and arranges it in such a way that the student can have little difficulty in mastering it. For the engineer who looks for theoretical considerations, there is ample food for reflection. The descriptions of the general theory of various turbines are remarkably clear, and are assisted by diagrams and woodcuts. To those engaged in the design of turbines the volume must be invaluable.

Mr. Bolton's book on "Motive Powers" is of a very different nature, and belongs to that large number of text-books written under the impression that a mere stringing together of "facts, formulæ, and data" is of service to the non-technical reader. The choice of a motor for any particular duty, of course, largely depends on various circumstances, and these must be considered by a qualified engineer. It is questionable whether any amount of study can qualify a non-technical man to make a suitable choice in such a matter. The book, however, contains a large store of information suitable for engineers, and it is arranged in a way that easy reference is possible, which is an important consideration. The author very properly falls foul of the term "nominal horse power," a useless term, and one very likely to mislead. It is quite time that steam and other engines were sold as representing the available power, or "brake horse-power." Under the head of power defined and compared, the author might have been more explicit in his definition of the relation between "the watt" and the "horse-power"; 746 watts are equal to

one *electrical* horse-power. In the chapter on the power of the wind, there is an interesting description of an electrical plant for lighting, which was used in London some time ago, the motive power being a windmill on the top of the building. There appears to be an opening for this type of motor. The author gives rules and tables for their design and construction.

Water-wheels, turbines, and hydraulic motors generally come in for a good deal of notice. The information given concerning these motors is very much condensed, but is in a useful form. "Molesworth's Pocket-book" is quoted for rules for the actual construction of turbines; Bodmer's book can be added with advantage. The question of labour and attendance has to be carefully considered in connection with the adoption of steam-power; a type of motor which, for small powers, is being discarded in favour of oil and gas engines. The steam engine, however, has points in its favour, simplicity of parts being not the least of them. The author gives a table showing relative values for heating purposes of various fuels; this is of value, and may prove of use to many steam users.

Under the heading of liquid fuel, no observations are to be found describing "Holden's System" for burning oil, tar, &c.: this should be added in a future edition. An essential feature of this work is a statement of the probable cost of the machinery described, thus rendering a comparison possible of alternate schemes. The condensation of exhaust steam from engines in large towns is an important question, because in some cases it may become a nuisance. The author describes the usual methods in vogue, but omits to mention the atmospheric condenser used to condense the steam, and so get rid of it. Steam engines of various kinds are fully dealt with, including those suitable for dynamo driving. Under the latter class we find no description of the Willan's central valve engine, probably the most efficient of any. If chapter xxi. is intended to include this engine, why not say so?

The author has much to say on the subject of different types of boilers. On page 179 we find a table giving the pitch of stays in flat surfaces in locomotive fire-boxes. This requires considerable alteration. The pitches given for the higher pressures and ½-inch plates are ridiculous; no locomotive builder exceeds 4¼ inches pitch with copper fire boxes. The usual hydraulic test for boilers is stated to be twice the working pressure. This is so in many cases, and we agree with the author that the boiler is needlessly strained. One and a half times the working pressure is ample, and is quite sufficient to test the workmanship. As to the general essentials for good boiler work, given on page 181, we cordially agree, but would add that machine flanging should, if possible, be done at one heat.

Much has been said of late about the virtues of the tubulous boiler. No doubt its convenience of transport is great, repairs are easily effected, and steam can be rapidly raised. The author gives some interesting data on these boilers, including the Belleville type now being adopted in this country.

Users of small power motors will be interested in chapter xxx. *et seq.* These deal with gas and oil engines, and contain some interesting information. Taken as a whole, this book contains a serviceable collection of data on various subjects. The volume should prove of use to engineers, who will find in it much information relative to motive powers.

N. J. L.

TRAVELS IN TIBET.

Diary of a Journey through Mongolia and Tibet in 1891 *and* 1892. By William Woodville Rockhill. 8vo. Pp. xx. and 414. Illustrations. (Washington: published by the Smithsonian Institution, 1894.)

Mr. Rockhill is no stranger to the British public; his admirable work on Tibet—"The Land of the Lamas," published in 1891—has been widely read, and his second great journey, described in the book now before us, earned for him the gold medal of the Royal Geographical Society, the highest geographical prize in the world. The book, as now published, differs from "The Land of the Lamas" by being less a piece of literature for general reading than a compendious record of observations suited for serious students of Central Asia.

Tibet is peculiar amongst the regions of the world by possessing almost every possible barrier to discourage the would-be explorer. Its physical conditions, lying in the centre of the largest continent, raised, though just without the tropic, into the frigid zone of altitude, composed in large part of rainless arid plains, girdled by the most stupendous mountains of the earth, conspire with the fanatical exclusiveness of its governing body to keep the land in seclusion. There have been fewer travellers in Tibet than in almost any other area of the known world. In his preface Mr. Rockhill recalls the deeds of his predecessors from Friar Oderic in 1325 to the Russian, French, and British travellers of the last decade. The last Europeans to reach the capital city of Lhasa were the Lazarist fathers, Huc and Gabet, in 1846. Since then the Indian native surveyor, Sarat Chandra Das, has succeeded in disguise in making a survey of the town, but every European has been successfully stopped and turned back at the entrance to Lhasa territory. Mr. Rockhill was no more fortunate in evading this fate than his predecessors were, or than his successor, Miss Annie Taylor, has been; but he was fortunate in being able to give an excellent account of the portions of the country which he visited. Mr. Rockhill has the almost unique attainment of knowing both the Chinese and the Tibetan literary languages perfectly; consequently he was able to make his own negotiations with the natives, and to obtain information from them at first hand. It is gratifying to find that one result of his careful study of Tibet is to vindicate the general truthfulness of the Abbé Huc's picturesque description of the country and the people, which is really responsible for such popular knowledge of Tibet as exists in European literature, and on which some recent travellers, misled by bad interpreters, had cast serious doubts.

Mr. Rockhill describes his journey in the form of a diary, a form which throws all the details into equal and somewhat undue prominence, demanding very careful reading, and many references to different passages, before the

general bearing can be understood. A series of appendices containing vocabularies of the Salar, and San-Ch'uan T'u-jen languages, a list of the plants met with, compiled by Mr. W. Botting Hemsley, a table of latitudes and altitudes, and a few meteorological statistics, in some measure makes up for the defects of the diary form. The index, which is all-important in a book of this kind, is unsatisfactory: the entries are numerous enough, but they are not descriptive. The mere facts that snow is referred to on twenty-eight specified pages, and sandstone on forty, does not assist the reader in the way a well-arranged index should. On the other hand, the illustrations are excellent, and leave nothing to be desired, except indeed that they were more numerous.

A map, on the generous scale of thirty-two miles to an inch, gives details of the route, but it is confined to Mr. Rockhill's own surveys, all outside being left blank.

Mr. Rockhill left Pekin in the hope of crossing Tibet from north to south, by a road leading to India, without touching Lhasa territory. He accordingly made his way through Mongolia, passing by Ordos and Alashan, up the valley of the Yellow River to Hsi-ning, and collecting the necessary material for a long desert journey, he left Lusar (Kumbum) on February 17, 1892, passed westward through the marshes of Tsaidam, and at the Naichi Gol, on May 17, turned south-westward with guides who had agreed to take him across the mountains to the Tengri-nor. It was a severe journey: grass for the horses and mules was often scarce; snow fell at midsummer, and herds of wild-yaks and wild-asses were the only living creatures to be seen. The snow-line appeared to be about 17,000 feet, but no glaciers were to be seen on any of the mountains. At length, on July 6, after three days' travelling without food, supporting life only on tea, the party sighted the tents of the Namru Tibetans, about two days' journey from the Tengri-nor. Here there was safety from starvation, but the tribe being under the government of Lhasa, the inevitable result followed. The tribe mustered sixty or eighty armed men, and with the utmost courtesy the head men, reinforced by officials from Lhasa, forbade any advance southward. After much talking, Mr. Rockhill secured the alternative of returning as he came, or going eastward to China *via* Ta-chien-lu, which was reached on October 1. By avoiding the high road, Mr. Rockhill succeeded in surveying a good deal of new country, and he made many most interesting observations on the people, who in south-eastern Tibet are much more liberal and enlightened than in the neighbourhood of Lhasa.

On returning to Shanghai the traveller found that in the eleven months since he had left it he had travelled 8000 miles, of which he had surveyed 3400 miles, and crossed 69 passes, all more than 14,500 feet above the sea. Three hundred photographs were taken, and between three and four hundred ethnological specimens collected. The journey was in fact a great and a successful one, though it led to no sensational discoveries; and we believe that the work of the American traveller from the east will bear the closest comparison with that of the Russian explorers from the north, and the British and Indian surveyors from the south.

Hugh Robert Mill.

MIND AND BODY.

The Philosophy of Mind; an Essay in the Metaphysics of Psychology. By G. T. Ladd, Professor of Philosophy in the Yale University. (Longmans, Green, and Co., 1895.)

PROF. LADD'S latest book opens with two excellent chapters on the connection between psychology and the philosophy of mind, which lead one to hope great things of the rest of the work. It is refreshing to find an author deliver an energetic and effective protest against the "water-tight compartment" theory—that science, and even the science of psychology, can get on without metaphysics—and then turn round and declare in favour of a good healthy realism. It is a psychological fact which is well worth keeping in mind, that we all naturally are, and, even in spite of philosophic training, in our ordinary life remain, dualistic realists. This metaphysical position is implied in all the language of science; so that, in particular, it is well-nigh impossible to interpret the results of psycho-physics in any other sense. His arguments against the view of consciousness as a mere series of passive states, which he attributes to Prof. James, are well worthy of attention, and further great expectations will be raised in the mind of the reader by the heading of the fifth chapter—"The consciousness of identity, and so-called double consciousness." For surely it is time that professed psychologists should give up ignoring the alleged facts of multiple personality and the various phenomena connected with "suggestion" and "hypnotism." Whence are we to learn about the psychological import of these things if not from them? But the expectation is unfortunately doomed to disappointment. After making some show of attacking the question, and expressing a pious belief that "the explanation of double-consciousness, when the facts are ascertained and the explanation is made, will be found in extension rather than reversal of the principles already known to apply to the normal activity of body and mind" (p. 168), he "feels obliged for the present to maintain a position of reserve." He admits, indeed, that if an individual should alternate from one condition to another, between which no actual connection by way of self-consciousness, memory, or thought could be traced (and, presumably, *à fortiori*, if both conditions should co-exist and manifest themthemselves by different channels, *e.g.* by speech and so-called "automatic" writing), we should have a true case of "double Ego." But he goes on to declare that "no such case, so far as the evidence is as yet sifted and understood, has ever occurred." It cannot be supposed that a professor of psychology has never come across the evidence; we can, therefore, only suppose that he relies upon the efficacy of his saving clause; for such cases have certainly been reported in abundance, though it may be that the evidence with respect to them is not yet thoroughly "sifted and understood."

The main thesis of the book, however, is the duality of body and mind; or, at least, the defence of natural dualism against such rival theories as Prof. Ladd conceives to be arrayed against it. It may, however, fairly be doubted whether any materialist, spiritualist, or monist would recognise his own theory among the dummies which Prof. Ladd puts up to knock down again.

He admits, in a note, that it is not likely that any one could be found to espouse the cause of what he calls materialism. The most effective answer he has to give to "monistic spiritualism," that if consistently argued out it would lead to solipsism, applies rather to idealism than to the animism against which the rest of his argument is directed. To his polemic against monism it might be objected, as to that against materialism, that no one would be found to defend the views attacked—at least, surely no one who believed, not only in body and mind, but in a third entity also, which is neither (even if this entity is "unknown and unknowable"), could call himself a *Monist*. Monism, as ordinarily understood, is the view, or hypothesis, that the *Träger* of conscious states is just the brain, and nothing else, and conversely that consciousness is a manifestation or aspect of certain brain activities. No third being is required where not even two are postulated. The rest of the argument against monism is to the effect that the supposed psycho-physical parallelism is not completely proven which may be admitted—and even that in some cases it can be shown not to exist, a point on which Prof. Ladd's arguments hardly seem conclusive. The weakest part of the argument, however, is the implied idea, so common in philosophical discussions, that a metaphysical theory to be accepted ought to be capable of rigid demonstration, instead of being of the nature of an hypothesis postulated to explain the facts of consciousness, which can never be absolutely proved, but may be believed in with greater or less strength of conviction. It is therefore no argument against the monistic hypothesis to say we cannot yet, and probably never will be able to, trace the psycho-physical parallelism everywhere.

The most curious thing in the book remains, however, to be told. In its last pages the author admits not only that "this dualism is not the final word," but that "it must undoubtedly be dissolved in some ultimate monistic solution"! And it must be a little annoying to the monists, whom he has so bitterly attacked, to find that this is a problem which "this treatise hands over to the larger and all-inclusive domain of philosophy."

EDWARD T. DIXON.

OUR BOOK SHELF.

The Story of "Primitive" Man. By Edward Clodd. Pp. 206. (London: George Newnes, Limited, 1895.)

A BOOK such as this forms a useful stepping-stone to higher knowledge; it creates interest, and develops a desire for further information, therefore it possesses the chief qualities that go to make a good book for the average man. For the reader who wishes to know more about the subject than can be compressed in two hundred small pages, a list of books is given at the end of the volume. The illustrations are numerous, but some of these are badly printed. The text is very attractively written, scarcely a sentence being beyond the comprehension of the popular mind. Though the story is briefly told, we have no doubt it will prove interesting to a wide circle of readers. It may be well to point out that the remarks with reference to the chipped flints found in what was believed to be an Upper Miocene deposit in Further India (pp. 23, 24), will need modification when the book comes to a second edition, the bed in which the flints occur having been shown to be Pliocene (see NATURE, vol. li. p. 608).

Britain's Naval Power. By Hamilton Williams. (London: Macmillan, 1894.)

THIS little volume ought to prove very useful to those who wish to know the chief events in the rise of Britain's naval power, without having to plod through details of little consequence. All the great battles are described, and plans of the actions are supplied with them. Celebrated single actions are also mentioned, and although, as the author himself states, some parts require revision and slight corrections, the volume is altogether a light and readable history of the first line of defence, to be commended to every one who desires to know something about naval battles without undertaking a systematic study of the subject.

Portraits berühmter Naturforscher. (Wien und Leipzig: A. Pichler's Witwe and Sohn.)

THE forty-eight portraits which, with short biographical sketches, make up this album, represent well-known men of science of the past and the present. With one or two exceptions, the plates are finely engraved from good portraits. Among our own countrymen in the collection are Darwin, Faraday, Sir William Herschel, Newton, Lord Kelvin (who is given his old and better-known name), and Tyndall.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

Discovery of Aboriginal Indian Remains in Jamaica.

THE island of Jamaica, at the time of its discovery by Columbus in 1494, is estimated to have been inhabited by about 600,000 natives, belonging to the race of the Arawâks—a people of simple habits and of a peaceable disposition. The barbarous and cruel treatment of these Indians by their Spanish conquerors, so rapidly decreased their numbers, that in 1655, the date of the conquest of the island by the English, it is probable that not a single specimen of the original type of inhabitant remained alive. Very little was left behind as a record that ever such a race existed here. A few pieces of earthenware showing very primitive ornamentation, and a few flint implements and beads, are practically all that remain to represent their arts and manufactures. Parts of the interior of the country are formed of Miocene limestone, and in this, many caves are to be found. Most of them have, however, yielded little of interest. In one, at Pedro Bluff, the only two aboriginal skulls hitherto known were found. These were submitted to Sir William Flower, and show a frontal compression with corresponding lateral expansion, a deformation produced artifically during infancy by the former inhabitants of the West Indian islands. A kitchen-midden at Northbrook, investigated by Lady Blake, has yielded pieces of ancient pottery, flint implements, shells, and bones of the Jamaica coney, *Capromys brachyurus*, Hill.

Great interest has been aroused in the island within the past few weeks by the discovery of a cave containing the skeletons of at least twenty-four individuals; the ages varying from that of a child with the permanent dentition not yet appearing, to that of aged persons with the teeth-sockets obliterated. Many of the skulls in their depressed frontal region resemble those from Pedro Bluff, and are, no doubt, aboriginal in type. There is, however, considerable variation in the amount of compression. Four of the skulls have been taken to England by Mr. Cundall, the Secretary of the Jamaica Institute, to be submitted to Sir William Flower.

A somewhat shattered canoe, about 7 feet long and 1½ feet wide, made of cedar-wood, was lying above many of the skeletons. An outer portion of the trunk of an *arbor-vitæ*, probably serving at one time as a "mortar," scarcely shows any signs of decay, as a result of the three or four hundred years it may have been in the cave. Among the remains were also obtained the perfect skulls and other parts of the skeleton of two coneys; two large marine shells (*Fusus* and *Murex*), soft parts of which are still eaten by the natives; numerous land shells (*Helix*), and insect remains.

Two small, nearly perfect, earthenware vessels were also found, similar to those known to have been made by the Arawâks. One of these *sappooras* is oval in shape, 7 inches in length and 2 inches high, with a rude handle at each end: the other is round, with a small ledge below the upper margin. Along with these were fragments of pottery belonging to a much larger specimen.

The cave was discovered by the Rev. W. W. Rumsey on the Halberstadt estate belonging to Mr. Gossett. It is in a wild rocky part of the Port Royal Mountains, at a height of about 2000 feet above the sea. The narrow entrance in the face of the hill-side was blocked by boulders of limestone. On removing these, a cavern with waterworn sides, partially covered with stalactitic deposits, was displayed, penetrating into the rock for a distance of about 20 feet, and in some places two or three feet high. The floor is covered with a deposit about 12 inches thick, of a fine, light yellowish dust, but the remains were superficial.

The size of the cave is not such as could possibly contain the whole of the individuals when alive, so that it is probable that it must have been used at one time as a burial-place; while the presence of the canoe, mortar, earthenware, coney bones, marine shells, and a flint implement, is suggestive that some of the people may have lived or fled there for safety, and perhaps been immured by their destroyers, the Spaniards. Whatever may be the explanation of their occurrence, the acquisition of the remains, which have been presented to the Museum, will be a great addition to the archæology of Jamaica.

Museum, Jamaica, May 28. J. E. DUERDEN.

The Antiquity of the Medical Profession.

WITH reference to Mr. H. Spencer's article on the evolution of the medical profession, in the *Contemporary Review* for June, it may be inferred that his remarks should only apply to its historical state in Britain, and not to that in European countries.

It may be pointed out that the profession had existed many centuries before that epoch in the Roman and Grecian nations, as may be seen by any one in looking over Lemprière's Dictionaries.

We have their medical works handed down to us in Celsus (14 A.D.) and Hippocrates (422 B.C.); likewise the Greek army at Troy (1184 B.C.) had military surgeons (Machaon); and Prof. Simpson had discoursed on those in the Roman armies—papers indicated 1856.

See also Dr. Smith's Dictionary, "Greek and Roman Antiquities," for articles on the subjects under:—Art. Medicus, art. Medicina, art. Chirurgia, art. Physiologia.

The art of medicine seems to have been ushered off the stage in the Dark Ages, and to have been consigned to the care of the monasteries and monks for a long period.

It would seem then, from history, that the medical profession is quite as old as either that of theology or law.

Edinburgh, June 17. W. G. BLACK.

A History of British Earthquakes.

ON two or three occasions you have allowed me to ask the readers of NATURE for aid in studying recent British earthquakes, and I have gratefully to acknowledge the valuable assistance which I have thus obtained.

If I might trespass once more upon your space, I should be glad to mention that I am now preparing a history of British earthquakes during the nineteenth century, and would thankfully receive notices of any shocks, either past or future, which your readers may be able and willing to send me. Extracts from provincial newspapers, from private diaries, or from any other trustworthy source, would be most useful.

With a view to aiding in the more careful observation of earthquakes in the future, I have drawn up a short paper of suggestions, and this I shall be happy to send to any one who may wish for it on receipt of his name and address. Those who desire to examine accounts of recent earthquakes in this country, I may refer to the *Proceedings* of the Royal Society for 1894, the *Quarterly Journal* of the Geological Society for 1891, and the *Geological Magazine* for 1891–1893. CHARLES DAVISON.

373, Gillott Road, Birmingham, June 17.

TERMS OF IMPRISONMENT.

IT would have been expected that the various terms of imprisonment awarded by judges should fall into a continuous series. Such, however, is not the case, as is shown by Table I., which is derived from a Parliamentary Blue-book recently published under the title of "Part I.—Criminal Statistics," p. 215. The original has been considerably reduced in size; first, by limiting the extracted data to sentences passed on male prisoners without the option of a fine, and, secondly, by entering the number of sentences to the nearest tenth or hundredth, as stated in the headings to the columns. The material dealt with is thereby more homogeneous than in the original, and its significance is more easily seen. The number of cases is amply sufficient to afford a solid base for broad conclusions, there being in round numbers 830 sentences for various terms of years, 10,540 for various terms of months, and 43,300 for various terms of weeks. The diagram drawn from Table I. gives a still clearer view of the distribution of these sentences:—

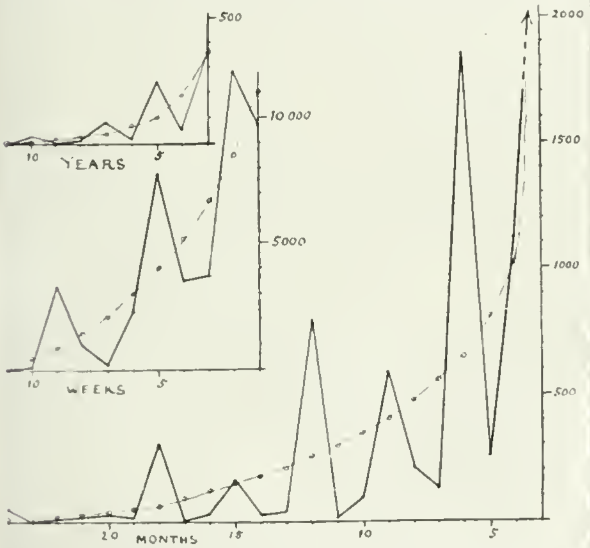
TABLE I. *Distribution of Sentences.*

Length of sentence.	One tenth (to nearest integer) of the number of sentences.		Length of sentence.	One tenth (to nearest integer) of the number of sentences.		Length of sentence.	One tenth (to nearest integer) of the number of sentences.		Length of sentence.	One hundredth (to nearest integer) of the number of sentences.	
Years.	Recorded.	Smoothed.	Months.	Recorded.	Smoothed.	Months.	Recorded.	Smoothed.	Weeks.	Recorded.	Smoothed.
16–	0		24–	5	1	10–	9	34	11–	0	0
15–	1		23–	0	2	9–	59	40	10–	1	5
14–	1		22–	1	2	8–	21	47	9–	33	9
13–	0		21–	2	3	7–	13	56	8–	10	14
12–	1		20–	3	4	6–	185	65	7–	2	21
11–	0	1	19–	2	5	5–	26	81	6–	23	30
10–	3	1	18–	30	6	4–	112	102	5–	77	40
9–	0	2	17–	0	9	3–	480	480	4–	35	52
8–	1	3	16–	3	12				3–	37	67
7–	8	4	15–	16	14				2–	118	85
6–	2	7	14–	3	17				1–	97	110
5–	24	10	13–	4	20						
4–	6	19	12–	79	25						
3–	36	36	11–	1	29						
	83	83		149	149		905	905		433	433

NOTE.—In reading the table, "16–" means "16 and above 15"; "15–" means "15, and above 14"; &c. The number of these intermediate cases being presumably insignificant, they are not noticed in the diagram, where all cases are referred to the upper of their limiting values.

The extreme irregularity of the frequency of the different terms of imprisonment forces itself on the attention. It is impossible to believe that a judicial system acts fairly, which, when it allots only 20 sentences to 6 years imprisonment, allots as many as 240 to 5 years, as few as 60 to 4 years, and as many as 360 to 3 years. Or that, while there are 20 sentences to 19 months, there should be 300 to 18, none to 17, 30 to 16, and 150 to 15. The terms of weeks are distributed just as irregularly. Runs of figures like these testify to some powerful cause of disturbance which interferes with the orderly distribution of punishment in conformity with penal deserts.

On examining the diagram we are struck with the apparent facility of drawing a smooth curve, that shall cut off as much from the hill-tops of the irregular trace as will fill their adjacent valleys. This has been done, by eye, in the diagram, the small circles indicating the smoothed values. Care has been taken that the sums of the ordinates drawn to the smooth curves should be equal to sums of those drawn to the traces, as is shown by the totals in the bottom line of Table I. The smoothed curves may therefore be accepted as an approximate rendering of the general drift of the intentions of the judges as a whole, and show that the sentences passed



by them severally, ought to be made more appropriate to the penal deserts of the prisoners than they are at present. The steep sweeps of the curves afford a strong testimony to the discriminative capacity of the judges, for if their discrimination had been *nil* and the sentences given at random, those steep curves would be replaced by horizontal lines. We have now to discuss the disturbing cause or causes that stand in the way of appropriate sentences.

The terms of imprisonment that are most frequently awarded, fall into rhythmic series. Beginning with the sentences reckoned in months, we see that their maxima of frequency are at 3, 6, 9, 12, 15, and 18 months, which are separated from one another by the uniform interval of 3 months, or a quarter of a year—a round figure that must commend itself to the judge by its simplicity. And we may in consequence be pretty sure that if the year had happened to be divided into 10 periods instead of 12, the exact equivalent of 3 months, which would then have been $2\frac{1}{2}$ periods, would not have been used in its place. If this supposition be correct, the same penal deserts would have been treated differently to what they are now.

Thus the precise position of the maxima has been apparently determined by numerical fancy, and it seems that the irregularity of the trace is mainly due to the award of sentences being usually in terms of the 3-monthly, but sometimes in that of the 1-monthly, series. The trustworthiness of this solution is tested by grouping the entries in sets of three, each set having one of the maxima for its middle member, as shown in Table II. (where, however, the first and last entries are perforce limited to sets of two). The agreement between the recorded and the smoothed entries is now passably good; it would become somewhat closer if the smoothed curve were revised by paying regard to the series of sets of three, thereby taking facts into account that were not utilised before.

TABLE II. (derived from Table I.).

Terms of sentence in months.	Number of sentences.	
	Recorded.	Smoothed.
24 and 23	5	3
22 — 20	6	9
19 — 17	32	20
16 — 14	22	43
13 — 11	84	74
10 — 8	89	121
7 — 5	224	202
4 and 3	592	582
	1054	1054

This solution does not, however, account for all the peculiarities of the irregular trace. For instance, in the original table in the Blue-book, absolutely not a single sentence of 17 months has been recorded, although there are 32 sentences of 16 months, and 340 of 18. I account for the absence of the number 17, by the undoubted fact that almost all persons have a disposition to dwell upon certain numbers, and an indisposition to use others, and that 17 is one of the latter. These curious whimsies become conspicuous whenever calculators, who are not forewarned, are set to record long series of measures, entering them *by estimation* to the nearest decimal of the divisions of the scale they use. Each figure from 0 to 9, in the decimal place, ought then to occur with equal frequency, but they never do; there is always a run upon some figures, while others are hardly, if ever, introduced. The fancies in this respect of different persons differ widely; the biblical Jews, for example, were fond of 40, apparently employing it as a noun of indefinite multitude, but it has no preferential use with us. On the other hand, it is probable that a large and awkward prime number, such as 17, would be generally in disfavour.

As regards the sentences reckoned in years, they range from 3 years upwards (those between 2 and 3 years being here reckoned as 3 years, while those below 2 years are reckoned, as above, in months). The maxima of frequency in this group are at 3, 5, 7, and 10 years, showing a tendency to a unit of 2 years at first, and then, presumably guided by the habit of decimal notation, to jump from 7 to 10. The bias due to decimal notation is forcibly shown by some entries in the original table which fall outside the limits of Table I. It there appears that 7 sentences were awarded for 20 years, and 6 for 15 years, but absolutely none for the 4 intermediate years, 19, 18, 17, 16. It should be added that there were also 8 sentences for 14 and for 12 years respectively. Had these appeared in Table I., they would have been entered to their nearest tenths, that is as 1 in each case, but I did not care to enlarge the table for the sake of including these, comparatively few, additional cases.

The sentences in terms of weeks have their maxima at 2, 5, and 9, for reasons which I do not as yet understand sufficiently to write about.

The general result is that if the judges were to act on uniform rules, the curve of distribution of terms of sentence would be mainly dependent on two sets of causes only, and would become much smoother in consequence. These are: (1) The distribution of true penal deserts; (2) errors of estimation, which would be distributed about each point in the true curve, according to the ordinary law of frequency of error, and with a modulus that might perhaps be determined.

It would be interesting to tabulate the sentences passed by the several judges since their appointments, to discover their respective peculiarities and personal equations, all who exercise extensive jurisdiction in criminal cases being included under the title of judge. We test the acquirements of youths by repeated examinations, but do not as yet employ the methods of statistics to test the performances of professional men. Examiners, for example, should themselves be tested in this way, and I have a fancy that a discussion of the clinical reports at the various large hospitals might enable a cautious statistician to express with some accuracy the curative capacities of different medical men, in numerical terms. Before putting oneself into the hands of any new professional adviser, it would certainly be a grateful help to know the indexes of capacity of those among whom the choice lay, not merely such as might be inferred from their performances in school and undergraduate days, or by their unchecked professional repute, but as they really are in their mature and practical life.

I will conclude by moralising on the large effects upon the durance of a prisoner, that flow from such irrelevant influences as the associations connected with decimal or duodecimal habits and the unconscious favour or disfavour felt for particular numbers. These trifles have been now shown on fairly trustworthy evidence to determine the choice of such widely different sentences as imprisonment for 3 or 5 years, of 5 or 7, and of 7 or 10, for crimes whose penal deserts would otherwise be rated at 4, 6, and 8 or 9 years respectively.

FRANCIS GALTON.

PROFESSOR FRANZ NEUMANN.

As already announced (p. 133) Prof. Neumann, the eminent physicist and mathematician, died on May 23 at Königsberg at the age of ninety-seven. At a recent meeting of the Paris Academy, the Secretary, M. Bertrand, in announcing the loss the Academy had sustained by the death of such a distinguished Correspondent in the Geometry Section, pronounced the following short *éloge* on Prof. Neumann's contributions to knowledge:—

"Franz Neumann, Professor of Physics and Mineralogy at the University of Königsberg, made his *début* in science more than seventy years ago, by some beautiful works on mineralogy. Soon after he directed his studies towards physics, and by an admirable 'Mémoire sur la Théorie des Ondulations,' which was presented to the Berlin Academy in 1835, he took his place among the masters of science. Neumann, like Cauchy, but by very different means, was led to consider luminous vibrations as taking place in the plane of polarisation, while Fresnel thought them perpendicular; he knew how to follow in the most minute details, always in accordance with the observation, the mathematical consequences of his hypothesis. But Fresnel's theory is not contradicted by any of the experiments, so doubt continues, and the ever renewed discussions, whatever their conclusion may be, will remain a noble homage to the man of science and profound physicist who was the first to start them.

"Neumann's memoir on induction showed again the great mathematical skill of its author. In it Neumann translated, by general formulæ, the discoveries of Faraday and Lenz's laws; it is to him that we owe the expression of the potential of a system of two closed currents, of which merely the existence, independently of the very elegant form which he has given it, has played such a great part in science.

"Franz Neumann was a great Professor. Even at the age of ninety he attracted numerous auditors; his lessons, received and written out by learned students, have been studied in all the universities of Europe. The study of physics was his aim; but when he came across a fine mathematical problem, he excelled in interesting his auditors by initiating them occasionally into the highest theories of analysis. It is with justice that in 1863 the Section of Geometry, making amends for a long neglect, elected this illustrious physicist into the Academy."

NOTES.

The annual meeting of the Royal Society for the election of Fellows was held on Thursday last, when the following gentlemen were elected into the Society:—Mr. J. Wolfe Barry, C.B., Prof. A. G. Bourne, Mr. G. H. Bryan, Mr. John Eliot, Prof. J. R. Green, Mr. E. H. Griffiths, Mr. C. T. Heycock, Prof. S. J. Hickson, Major H. C. L. Holden, Dr. Frank McClean, Prof. William MacEwen, Dr. Sidney Martin, Prof. G. M. Minchin, Mr. W. H. Power, Prof. T. Purdie.

Mr. C. C. Harrison has presented a sum of £100,000 to the University of Pennsylvania, in memory of his father, Dr. George Lieb Harrison. The fund is to be known as the "George L. Harrison Foundation for the Encouragement of Liberal Studies and the Advancement of Knowledge." Only the income from the fund can ever be used, and it must be devoted to the establishment of scholarships and fellowships intended solely for men of exceptional ability; to increasing the library of the University, particularly by the acquisition of works of permanent use and of lasting reference to and by the scholar; to the temporary relief from routine work of professors of ability in order that they may devote themselves to some special work; or to securing men of distinction to lecture and for a term to reside at the University.

Science gives the following as the preliminary arrangements for the forty-fourth meeting of the American Association for the Advancement of Science, to be held in Springfield, Mass., from August 28 to September 7, 1895:—At the first general session the President-elect, Prof. E. W. Morley, will be introduced by the retiring President, Prof. D. G. Brinton, who will afterwards give an address on "The Aims of Anthropology." The Presidents of the sections, and the subjects of some of their addresses, are as follows:—Section of Physics: "The Problem of Aerial Locomotion," W. Le Conte Stevens. Section of Anthropology: F. H. Cushing. Section of Geology and Geography: "The Geological Survey of Virginia, 1835–1841—its History and Influence in the Advancement of Geologic Science," Jed. Hotchkiss. Section of Economic Science and Statistics: "The Providential Function of Government in Relation to Natural Resources," B. E. Fernow. Section of Chemistry: McMurtie. Section of Botany: "The Development of Vegetable Physiology," J. C. Arthur. Section of Mechanical Science and Engineering: William Kent. The affiliated societies meeting in conjunction with the Association are:—The Geological Society of America: Prof. N. S. Shaler, President; Prof. H. L. Fairchild, Secretary. Society for Promotion of Agricultural Science: Prof. William Saunders, President; Prof. William Frear, Secretary. Association of Economic Entomologists. Association of State Weather Service: Major H. H. C. Dun-

woody, President; James Berry, Secretary. Society for Promoting Engineering Education: Geo. F. Swain, President; Prof. J. B. Johnson, Secretary. American Chemical Society: Edgar F. Smith, President; Prof. Albert C. Hale, Secretary. American Forestry Association: Hon. J. Sterling Morton, President; F. H. Newell, Secretary. Applications relating to membership and papers should be sent to Prof. F. W. Putnam, Permanent Secretary, Salem, Mass. For all matters relating to local arrangements, hotels, railway rates and certificates, Mr. W. A. Webster, Local Secretary. A. A. A. S., Springfield, Mass., should be addressed.

Mr. R. F. Stupart has succeeded the late Mr. C. Carpmael, as Director of the Meteorological Service of Canada.

The Grocers' Company have renewed the research scholarship held by Mr. Leonard Hill, and have elected Dr. J. Haldane and Prof. Waymouth Reid to the places vacated by Dr. Vaughan Harley and Dr. E. Stirling. The scholarships are each of the value of £250 a year.

At the annual meeting of the London Library, held on Friday last, Mr. Herbert Spencer was elected a vice-president, and Prof. Huxley was elected a member of the committee. A scheme for the reconstruction and extension of the premises, at an estimated cost of £17,000, was discussed and adopted, and it was decided to commence the work when a sum of £5000 has been obtained by means of donations.

The Organising Committee of the International Congress of Applied Chemistry, to be held in Paris next year, met a few days ago to make preliminary arrangements. The Congress will be divided into ten sections, referring respectively to sugar refineries, distilleries and brewing industries, agricultural industries, agricultural chemistry, alimentation and public hygiene, chemical industries, chemical apparatus, metallurgical chemistry, photographic chemistry, and electro-chemistry.

The fifth annual conference of representatives of authorities under the Sea Fisheries Act was held on Friday last, under the presidency of Sir Courtenay Boyle. In the course of a few remarks upon the establishment of hatcheries for sea-fish by committees, or out of Imperial funds, Mr. Bryce pointed out that a great deal had been done by marine laboratories and stations for observation, to determine more fully the habits of the fish, and remarked that only by means of hatcheries, and by prohibiting the taking of undersized fish, was it possible to recreate the diminishing supply of our soles and other flat fish.

We notice with regret that Dr. Valentine Ball, C.B., F.R.S., Director of the National Museum, Dublin, died on Saturday, after a short illness. Dr. Ball was for seventeen years connected with the Geological Survey of India. On the resignation of the chair of Geology in the University of Dublin by Dr. Haughton, he was appointed to it, and twelve years ago he accepted the position which he held at the time of his death. He was the author of several valuable treatises, and while Director of the National Museum, he greatly added to the value of the collections.

Several exhibitions and congresses of scientific interest are noted in the *Board of Trade Journal* as having been lately projected. In connection with the thirteenth International Exhibition to be held at Bordeaux in September next, the Société Philomathique of the town will organise a congress of technical, industrial, and commercial instruction similar to that held in 1886, at which the English Government was officially represented. An international exhibition of articles of food, clothing, hygienic appliances, sport, and inventions of all kinds will be held at the "Parkhaus," Bremen, in the course of this year. It will be open from September 14 to October 6. An international exhibition will also be held in Montreal, Canada, next year. The exhibition will open in May, and close in October. It will be held on the site of the present exhibition grounds and on adjoining land of the Mount Royal Park, embracing altogether about 120 acres. The buildings will be twenty-seven in number, and will be devoted to fine arts, manufactures, and liberal arts, electricity, machinery, fisheries, forestry, horticulture, agriculture, &c. Finally, according to latest advices from Denver, the plans for the holding of a mining and industrial exhibition in that city, in the fall of next year, are being advanced with vigour and success.

The New York State Bridge Commission have approved the plan of Engineer Charles MacDonald for a steel suspension bridge from New Jersey to New York City. The bridge will be 5600 feet long, with a length of 3110 feet between piers; 125 feet wide, with room for six railroad tracks; and 150 feet above mean tidewater. The piers will be 557 feet high, supported by 125 feet of solid masonry. The cost is guaranteed not to exceed 25,000,000 dollars. The bridge will be much the largest suspension bridge ever attempted.

One of the most remarkable features of earthquake-pulsations is their great duration. The originating earthquake may last but a few seconds or minutes, while the ground at a distance may rock gently through a very small angle for several or many hours. Dr. E. Oddone, of the geodynamic observatory at Pavia, has recently contributed an interesting paper on this subject (*Rend. della R. Acc. dei Lincei*, iv., 1895, pp. 425-430). Making use of the records of distant earthquakes during the years 1893-94 by delicate seismometrographs at Rocca di Papa, Rome and Siena, he arrives at the important conclusion that the duration of the pulsations increases with the distance from the epicentre.

Some singular curves showing the distribution of daily wind velocities in the United States, are published by Mr. F. Waldo in the current number of the *American Journal of Science*. The stations chosen range from the Atlantic to the Pacific and Mexican coasts, and include Block Island, New York, Cleveland, San Francisco, San Diego, North Platte, Fort Apache, Salt Lake City, and Roseburgh, among others. The months of January and July are selected as typical months for average daily variation. The daily variations are always greater in summer than in winter, except for Fort Apache, on the great plateau, where the excursions are about equal. At this place the velocities vary from 9·2 to 3·3 miles per hour in January, and from 10·1 to 2·9 miles per hour in July, the maximum in each case taking place at about 4 p.m., and the minimum at 8 a.m. The greatest variation of all is shown by the San Francisco curve for July. About 4 p.m. the wind blows with a speed of some 18 miles per hour, which falls to 7 miles per hour in the forenoon. Tatoosh Island shows a minimum at 2 p.m. in January, but its variations in July are similar to those at Block Island in the Atlantic, which shows the same sequence as the continental stations referred to, but with smaller amplitudes.

Two observations recorded by Mr. W. C. J. Butterfield, in the *Zoologist*, give support to the view that individual female Cuckoos only introduce their eggs into the nests of one particular species of birds, and not indiscriminately into those of any of the birds usually selected as foster-parents. Mr. Butterfield took a Cuckoo's egg from a Wren's nest in the early part of May, and three weeks later found another Wren's nest within a few yards of the former one, also containing a Cuckoo's egg. The two eggs were exactly alike, both as to size, and as to the manner in which the colouring matters and markings were disposed. It is therefore most probable that the eggs were laid by the same bird; for it is well known that a strong family likeness exists between the eggs laid by the same individual, although the eggs of different individuals of the same species

may vary considerably. The observation thus affords another instance of a Cuckoo placing its egg in the nest of a particular species of bird, although there were numerous nests of Hedge-Sparrows and other dupes of the bird in the vicinity, into which the egg could have been put with much less difficulty.

A story to the effect that a new breed of cats had been produced in the cold-storage warehouses of Pittsburg went the rounds of the newspapers some months ago, and was reprinted in most of our scientific contemporaries. It has even found its way into Mr. Lydekker's recent volume on "Cats." A letter received from the Secretary of the Cold Storage Co., and published in the June number of the *American Naturalist*, shows that the story has but a slight foundation in fact. The letter reads as follows:—"While there is some foundation for the newspaper article, it is somewhat exaggerated. Our cold-storage house is separated into rooms of various sizes, varying from 10° to 40° above zero. About a year ago we discovered mice in one of the rooms of the cold-storage house. We removed one of the cats from the general warehouse to the room referred to in the cold-storage house. While there, she had a litter of several kittens; four of these were transferred into one of the general warehouses, leaving three in the cold-storage house. After the kittens were old enough to take care of themselves, we put the old cat back into the house we had taken her from. The change of climate or temperature seemed to affect her almost immediately. She got very weak and languid. We placed her again in the cold-storage room, when she immediately revived. While the feelers of the cats in the cold-storage room are of the usual length, the fur is thick and the cats are larger, stronger, and healthier than the cats in any of the other warehouses." Thus, it is pointed out, the only result of the change of environment was the usual one which ensues on the advent of winter in extra-tropical latitudes generally.

Herr H. Schinz reprints from Engler's *Botanisches Jahrbuch*, vol. xxi., a synopsis of the African Amaranthaceæ, in which a number of new species are described.

The most recent part published (No. 7) of Dr. George King's "Materials for a Flora of the Malayan Peninsula," published in the *Journal* of the Asiatic Society of Bengal, is occupied by the orders *Meliaceæ*, *Olacineæ*, and *Ilicineæ*. A large number of new species are described, and a new genus, *Bracea*, belonging to the Olacineæ.

In an article reprinted from the *Ann. de la Société belge de Microscopie*, M. E. Marchal discusses the microbiological processes which take part in the ripening of soft cheeses, especially those known as "fromage de Herve" and "fromage Casette." While a large number of microbes appear to assist in the process, he states that the essential part is played by the fungus known as *Oospora lactis*, Sacc.

In a previous note (vol. li. p. 540), we have given a brief account of the Vicentini microseismograph erected in the University of Siena. A full description of the instrument, illustrated with three figures, has now been published by the inventor (*Bull. Soc. Veneto-Trentina di Sci. Nat.* vi., 1895), and well deserves the attention of seismologists.

We are glad to observe that the South London Entomological and Natural History Society reports a prosperous condition, in the volume of *Proceedings* for the year 1894. The Society dates back to 1872, and has been a centre of scientific energies ever since its foundation.

The papers read at the fifth annual meeting of the Museums Association, held at Dublin a year ago, have just been published in a report of the proceedings at the meeting. The report, which is edited by Mr. E. Howarth and Mr. H. M. Platnauer, should be in the hands of all curators of museums.

The first number of a bimonthly journal for sanitary engineers will be published at Brussels on August 1, under the title *La Technologie Sanitaire*. It will be under the direction of an editorial committee, the secretary of which is M. Victor J. Van Lint, 115 rue Joseph II., Bruxelles. The journal will deal with all questions relating to public health.

A full abstract of a paper on "The Psychologic Development of Medicine," read by Dr. J. H. McCormick before the Johns Hopkins Hospital Historical Club, on April 8, appears in the *Johns Hopkins Hospital Bulletin*, No. 49. The paper follows almost exactly the same lines as Mr. Herbert Spencer's paper in the current number of the *Contemporary Review*.

The latest addition to the Encyclopédie Scientifique des Aide-Mémoire is "Transmissions par Cables Métalliques," by M. M. H. Léauté and A. Bérard. The transmission of power by metallic cables has given rise to important mathematical developments which are considered in this Aide-Mémoire. The authors confine themselves to the theoretical points which ought to be known to every engineer concerned with cable transmission.

To the series of Economic Classics in course of publication by Messrs. Macmillan, has just been added Thomas Mun's important treatise, "England's Treasure by Forraign Trade," written about 1630, and printed for the first time in 1664. The treatise marks an important period in the history of economic thought, and its author is regarded by political economists as the founder of the mercantile system. In the present reprint of the first edition of the book, the title-page is reproduced in facsimile, and the original spelling and punctuation are followed throughout.

The third part of "Phycological Memoirs," edited by Mr. George Murray, has just been published by Messrs. Dulau and Co. The memoirs are devoted to researches made in the Botanical Department of the British Museum (Natural History), and the present part contains papers on "A New Part of *Pachytheca*," "Calcareous Pebbles formed by Algæ," "The Sori of *Macrocystis* and *Postelsia*," and "A Comparison of the Arctic and Antarctic Marine Floras." Four very fine lithographed plates illustrate the papers.

The colours exhibited by the artificial spectrum-top, described and discussed in these columns some months ago, are shown much more distinctly, and in greater variety, by a "Betts's Chromoscope," sent to us by Messrs. George Philip and Son. The instrument consists of an ingenious whirling table, by means of which heart-shaped pieces of cardboard, having arcs of different thicknesses variously disposed upon them, are put in rotation. A moderate speed of rotation produces a very definite impression of coloured rings, and when some of the more complicated designs are used, secondary tints are clearly seen.

Messrs. J. and A. Churchill have published an eighth edition of the well-known "Bloxam's Chemistry, Inorganic and Organic," rewritten and revised by Prof. J. M. Thomson and Mr. A. G. Bloxam. Several new woodcuts have been added, and some obsolete ones have been omitted. Considerable changes have been made in the arrangement of the subject-matter, and a large portion of the book has been rewritten, while the whole of it has been well revised. The changes all appear to have been in the direction of improvement; hence the book will hold its place as a good text-book and a handy work of reference.

We have received from Dr. L. Palazzo an account of a meteorological station recently attached to the laboratories of the Public Health Department in Rome. The authorities, recognising the important connection between various diseases and atmospheric conditions, have provided the station with a full

set of instruments, and intend to instruct students belonging to the school annexed to the laboratories in their use, and to include, among other studies, a short course of meteorology as applied to hygiene. The results of the observations will be regularly published in a special bulletin, with a view to determining more particularly the medico-climatology of that city.

MISS E. A. ORMEROD has sent us a leaflet referring to the Forest Fly (*Hippobosca equina*, Linn.), a well-known trouble in the New Forest of Hampshire and its neighbourhood. This fly is to be found on various kinds of animals, as horses, donkeys, cattle, dogs, and cats, to all of which its presence in the hair is a severe annoyance. According to general belief, the fly feeds by blood-sucking; it is also said to find nourishment in the perspiration given off by cattle, but further investigation as to how far this occurs is required. The method adopted to prevent the attacks is to wipe the horses over with a cloth moistened with paraffin, or with some dilute sanitary solution.

WE have received a copy of Mr. W. E. Plummer's Report of the Observations made, under his direction, at the Liverpool Observatory, Birkenhead, during 1894. From observations of twenty-two stars, the latitude of the Observatory, for the mean epoch 1894·7, was found to be 54° 24′ 4″·8. A new longitude determination has also been made; exchange of signals with Greenwich Observatory on thirteen nights gave the value 12m. 17·33s. West of Greenwich. The long series of photograph records accumulated at the Observatory, has been used by Mr. Plummer for the derivation of the diurnal inequality of barometric pressure. The results of his investigation are stated in an appendix to the Report, and are clearly exhibited by means of curves representing the diurnal changes of the barometer in each month, and also for the year.

ONE after another, scientific societies are beginning to organise their literature. Quite recently, under the title "Bibliotheca Geographica," the first volume of a geographical bibliography has been published by the Berlin Gesellschaft für Erdkunde. The volume contains the titles of all the geographical publications during 1891 and 1892, classified into subjects, and each section arranged alphabetically according to the author's names. In general geography there are different classes for text-books, historical geography, mathematical and physical geography, biological geography, and anthropological geography (which covers colonisation and the distribution of disease). The classification adopted for purely geographical papers is very elaborate, and the work done in any region during the years covered by the bibliography can be very easily found. It is proposed to issue annual bibliographies similar to the present volume. The editor of the series is Herr Otto Baschin, and the first volume has been prepared with the assistance of Dr. Ernst Wagner.

THE Belgian Society of Geology, Palæontology and Hydrology, aided by Government and other subsidies, has published the first part of an elaborate rainfall investigation of that country, prepared by A. Lancaster, of the Royal Observatory of Brussels. The author is well known to men of science by various valuable publications, and it was entirely due to his efforts that the rainfall service in its present complete form was established in the year 1882. The complete publication will consist of two or three volumes, the first of which contains 224 octavo pages, accompanied by a map drawn by the Military Cartographical Institute, to the 400,000th of the true scale. The number of rainfall stations dealt with is 282, and the monthly sums and means are given for the whole period, together with a series of tables showing the geographical distribution according to catchment basins, and tinted charts showing various annual rainfall zones. The second part will contain various supplementary tables, such as the distribution of rainfall according to seasons, variability of rainfall, &c.; the expense of this part is to be defrayed from the proceeds of the sale of the first part, which is issued at cost price.

FROM the point of view of stereochemistry, the supposed impossibility of preparing optically active halogen compounds from the corresponding active hydroxy-acids has been a serious defect in the strong array of evidence which has compelled the acceptance of van't Hoff's hypothesis of the asymmetric carbon atom. This defect has at last been remedied by P. Walden, who describes a series of active halogen substitution products in the current number of the *Berichte*. Inquiring whether the inactivity of the halogen derivatives prepared by replacement of the hydroxyl group in active compounds by bromine or by chlorine, were due to an inherent quality of the halogen atom, or rather due to the racemisation of the compounds under the conditions hitherto employed in their production, the author undertook the task of examining the methods used in preparing these compounds. Working on the active hydroxy-acids: malic, tartaric, sarcolactic, and mandelic acids, the substitution of chlorine and bromine for hydroxyl was accomplished by means of phosphorus pentachloride and pentabromide respectively Under the conditions detailed by the author, this substitution was carried out without the racemisation which appears hitherto to have always occurred when these halogen derivatives have been prepared. He has shown that (1) dextro-rotatory chlor- or brom-succinic acid may be prepared from the ordinary Levo-rotatory malic acid; (2) lævo-rotatory tartaric acid yields Levo-rotatory derivatives of its esters, containing a halogen atom in place of a hydroxyl group, which retain the optical activity due to the presence of the asymmetric carbon atom; (3) similarly, dextro-rotatory derivatives of α-chloropropionic acid and α-bromopropionic acid can be obtained from the lævo-rotatory sarcolactic acid; and (4) lævo-rotatory mandelic acid (from amygdalin) yields dextro-rotatory phenylchloracetic acid and phenylbromacetic acid. These active compounds have hitherto only been prepared in the racemic form. Their observed inactivity when so prepared was not due to any accidental limitation of the generality of van't Hoff's theory, but only to the racemisation they had undergone during the process of preparation. It is probably quite generally possible to substitute halogen atoms for hydroxyl groups in combination with active asymmetric carbon atoms without destruction of their optical activity. The activity of the compound depends only on the fact of four different atoms or atomic groups being connected with one and the same carbon atom, while the amount and direction of the rotation produced is unquestionably related to the specific nature of these atoms and groups.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*, ♀ ♀) from India, presented respectively by Mr. Charles Roberts and Miss Wieldt; a Leopard (*Felis pardus*, ♀) from India, presented by Mr. Edward Langworthy; a Common Otter (*Lutra vulgaris*, ♂), British, presented by Mr. M. P. Clarke; a Northern Mocking Bird (*Mimus polyglottus*) from North America, presented by Mr. Henry J. Fulljames: a Yellow-throated Sparrow (*Gymnorhinus flavicollis*), a Double-banded Pigeon (*Treron bicincta*), two Chinese Quails (*Coturnix chinensis*), two White-breasted Gallinules (*Gallinula phœnicura*) from India, presented by Mr. Frank Finn; two Weka Rails (*Ocydromus australis*) from New Zealand, presented by Mr. Reginald Moorhouse; two Southern River Hogs (*Potamochœrus africanus*, ♂ ♀) from East Africa, presented by the late Mr. B. Ward; a European Pond Tortoise (*Emys europæa*), European, presented by Miss Laura Bedford; a Sharp-nosed Crocodile (*Crocodilus acutus*) from Jamaica, presented by Lady Blake; a Black-spotted Teguexin (*Tupinambis nigro-punctatus*) from South America, deposited; a Ring-tailed Phalanger (*Pseudo-*

hirus peregrinus) from Australia, two Nicobar Pigeons (*Calænas nicobarica*) from the Indian Archipelago, purchased; a Reticulated Python (*Python reticulata*) from Malacca, received in exchange; a Thar (*Capra jemlaica*, ♀), a Red Deer (*Cervus elaphus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OCCULTATION OF REGULUS.—On June 26 there will be an occultation of Regulus, magnitude 1·5. The disappearance will take place at 8.4 p.m., while the sun is still above the horizon, and the star will reappear at 8.56—that is, about 37 minutes after sunset at Greenwich. The point of disappearance will be at an angle of 147° from the north point towards the east, and of reappearance at 275 reckoned in the same direction. The age of the moon will be a little less than 4 days.

THE RECURRENCE OF ECLIPSES.—A new period of the recurrence of eclipses, which promises to be of great use in the discussion of ancient eclipses, has been investigated by Prof. J. M. Stockwell. (*Astronomical Journal*, No. 346.) He points out that 372 tropical years are very nearly equal to 4601 lunations, and also very nearly equal to twenty revolutions of the moon's node; thus:

372 tropical years	=	135870·10348 days.
4601 lunations	=	135870·23425 ,,
20 revolutions of node	=	135870·700 ,,

During this period, the change of mean longitude of the sun and moon at the time of new moon is $-5°·057$, of the longitude of the moon's perigee $+11°·464$, and of the longitude of the ascending node $+0°·021$. The precession of the equinoxes during 4601 lunations amounts to $5°·1368$, so that the mean longitude of the sun and moon when referred to the movable equinox only changes by $0°·0797$ in a period of 372 years. From this it follows that if an eclipse happened on a given day of the tropical year, there would be another eclipse on the same day of the tropical year 372 years afterwards.

As an example of the application of this new cycle, Prof. Stockwell gives particulars of an inquiry into an eclipse of the sun which is said to have been observed in China on the day of the autumnal equinox during the twenty-second century B.C. According to Oppolzer, an eclipse occurred at the autumnal equinox in the year B.C. 1039, October 3, and going back three periods of 372 years, the year 2155 B.C. is deduced; other eclipses about this time are found by adding multiples of nineteen years to that date. The discussion of the conditions shows that the eclipse which satisfies the tradition occurred on October 10, 2136 B.C.; this would be visible as a partial eclipse over nearly the whole of China. According to a well-known story, the astronomers Ho and Hi were put to death for having failed to predict this eclipse.

VARIABILITY OF NEBULÆ.—One of the best authenticated cases of a variable nebula is that discovered by Hind in 1852 in the constellation Taurus. The nebula was then easily seen in ordinary telescopes, but D'Arrest was quite unable to see it in October 1861, though it was detected shortly after as an exceedingly faint object in the Pulkowa refractor, and in the following year was seen a little brighter with the same telescope. In 1868, however, the nebula was invisible to Struve, but another nebula was discovered 4' preceding. Struve's nebula was subsequently observed by D'Arrest, who testified to its absence in previous observations of the neighbourhood; it was seen also by Tempel in November 1877, but was not visible to him a month later. The interest attaching to this region was revived when, in 1890, Mr. Burnham found that τ Tauri was involved in nebulosity; this was confirmed by Prof. Barnard, who also observed that Hind's nebula was only just visible with the Lick telescope, while Struve's nebula was not perceptible. In a paper recently communicated to the Royal Astronomical Society, Prof. Barnard states that on February 25 of the present year he found Hind's nebula to be an easy object, while Struve's nebula was unseen, and the nebulosity round τ Tauri had practically faded from visibility. Further observations on March 24 showed that Hind's nebula was again scarcely visible, while τ Tauri was distinctly nebulous, and a faint nebula was suspected in the position assigned to Struve's nebula (*Observatory*, June).

It thus appears that there are really three variable nebulæ in this region, and the observations rather suggest that there is a connection between them. In 1890, Prof. Keeler found that the nebulosity round τ Tauri was probably of the bright-line type, but nothing seems to be at present known as to the spectra of Hind's and Struve's nebulæ. On the meteoritic hypothesis, changes in the brightness of nebulæ are due to the interpenetration of nebulous streams and sheets.

THE ZI-KA-WEI OBSERVATORY.—The Zi-ka-wei (or Sicawei) Observatory, near Shanghai, was founded in 1873 by the French Roman Catholic Mission of Kiang-nan, and provided with the instruments necessary for the study of meteorology and terrestrial magnetism. Since that time, excellent service to commerce and to science has been rendered by the Observatory, by the daily publication of weather bulletins, and the issue of a number of important memoirs. Up to the present, however, astronomy has received little attention at Zi-ka-wei. Twelve years ago, the Municipal Council of the French Settlement furnished the Observatory with a small transit instrument for time determinations in connection with the time-ball service then established, but that instrument represents the whole astronomical outfit. Recognising this deficiency, Father Chevalier, the Director of the Observatory, has made an appeal for funds to purchase a good equatorial telescope. The English Settlement at Shanghai has voted a sum of £400 towards the cost of the instrument, and the French Settlement has granted a like amount. The shipping companies at Shanghai have also promised a sum of about £400, so that £1200 may be taken to be already available. But Father Chevalier wishes to have an instrument with an aperture of about twenty inches, and for this the money already subscribed is insufficient. He has therefore appealed to friends of science in France, America, and England for a sum of about £1000 more. If this is contributed, he hopes to have erected a great equatorial, and to accomplish valuable work with it.

THE ROYAL SOCIETY CONVERSAZIONE.

THE rooms of the Royal Society at Burlington House were filled last Wednesday evening, when the annual conversazione to which ladies are admitted took place. Some of the exhibits were shown at the conversazione on May 1, and have already been described in these columns. Following our usual custom, we only give descriptions of new exhibits.

Perhaps the most striking feature of the evening was the telephonic communication with Edinburgh, Glasgow, Belfast, and Dublin, practically shown by the Postmaster-General. The line used is the first link of the great Trunk Telephone System erected by the Post Office, which will eventually place the chief towns in the British Isles in direct communication with each other. The wires to Ireland extend through Leeds and Carlisle to Portpatrick, thence by cable across the North Channel to Donaghadee, and thence to Belfast and Dublin, the distance by this route from London to Dublin being 467 miles. The lines are so carefully laid that it was easy to converse with persons at the places connected by them, without being disturbed by the foreign sounds usually associated with telephonic communications.

An electograph for indelible linen marking was shown by Messrs. Nalder Bros. and Co. The instrument is used as follows: the fabric is damped and a current is passed for about two seconds from a silver die, carrying silver into the fabric wherever the die touches. The current is then reversed for three seconds, which reduces the silver in the fabric; the final result being the same as with ordinary marking-ink, viz. that metallic silver is deposited in the tissue. Plain water can be used, but a salt solution is preferable, as the result is much more quickly obtained.

Models illustrating Lewis and Hunter's patent coal shipping system, as in use at the Bute Docks, Cardiff, were exhibited by the Bute Docks Company. With this system the coal is shipped in very much better condition than with the old systems, and owing to the construction of the carrying-boxes, with a cone valve or bottom, which is only released to let the load out when it is lowered down into the hold of the vessel, within some 18 inches of the flooring of the ship or the cargo, as the case may be, the breakage is greatly reduced. Each crane is capable of loading 300 tons per hour.

Prof. C. V. Boys illustrated the projection of ripples, and showed a logarithmic chart of wave and ripple velocities and frequencies. Ripples produced by tuning-forks are so small, and travel so quickly, as to be invisible unless illuminated either instantaneously or intermittently at the proper rate. They are then visible, and the relations of velocity and frequency can be

illustrated. Both tuning-forks and a mechanical device were employed to produce the ripples. By the use of "scale lines," the logarithmic chart was made more comprehensive than usual. The lines were employed to illustrate the effect of all possible variations of gravity and of surface tension divided by density upon velocities and frequencies of waves and ripples.

Mr. J. Norman Lockyer, C.B., had three exhibits. One was a photograph of apparatus employed for collecting the gases obtained from minerals by the distillation method. A small retort containing the mineral is connected with an end-on spectrum tube joined on to a Sprengel pump. After exhaustion, the mineral is heated to redness, and the spectra of the gases evolved at the various stages, as exhibited by the spectrum tube, are both observed and photographed. The gases are collected in a "steeple" at the foot of the fall tube of the pump, and they can then be observed at atmospheric pressure. The second exhibit consisted of photographs of the spectra of Bellatrix, and of a part of the solar chromosphere, showing coincidences with the lines photographed in the spectra of the gases obtained from uraninite. The photographs showed a close relation of the new gas or gases to solar and stellar phenomena. They appear to point to the *vera causa*, not of two or three, but of many of the lines which so far have been classed as "unknown." The spectrum of Bellatrix was photographed at South Kensington with a 6-inch prism of 45°, and that of the solar chromosphere with the same instrument during the total eclipse of the sun, 1893. Mr. Lockyer also exhibited photographs of the spectra of the new gases. In the preliminary experiments, the new gases have not been separated from the known gases which come over with them, so that the spectra exhibited contained many known lines. The photographs illustrated: (*a*) The presence of the yellow line (D_3) in some instances *with* the blue line 4471, and in others *without* it. (*b*) The presence of the yellow line in some spectra *with* an ultra-violet line at 3889, and in others *without* it.

Dr. A. A. Common exhibited the following silvered glass mirrors: (1) 21-inch convex mirror, 54-inch radius, being the small mirror of an oblique Cassegrain reflecting telescope. (2) 20-inch concave mirror, 90-inch radius, spherical curve. (3) Two 16-inch plane mirrors for heliostats to be used at the 1896 total solar eclipse.

Mr. A. E. Tutton exhibited an instrument for cutting, grinding, and polishing accurately orientated plates and prisms of crystals of every degree of hardness. The instrument combines an accurate reflecting goniometer with a diamond-edged cutting disc and grinding and polishing laps. The adjusting segments of the goniometer are graduated, in order that the crystal may be adjusted so that the desired direction in it can immediately be brought parallel to the cutting disc or grinding lap. Numerous interchangeable laps are provided suitable for all classes of crystals, and the interchange may be effected with great readiness. A counterpoising arrangement is also provided which enables the pressure with which the crystal bears upon the lap to be nicely adjusted, according to the strength of the crystal. The instrument may either be driven by hand or by means of any form of small motor.

Mr. A. P. Trotter showed a model illustrating the relation of volts, amperes, and length of electric arc. The model was made from the diagrams in Prof. Ayrton's paper, read before the Chicago Congress, and described in Mrs. Ayrton's article in *The Electrician*. Drawings of the electric arc were shown by Mrs. Ayrton. The drawings were in sepia, and ten times the full size. They showed the form of the arc produced with a current of 20 amperes between a positive carbon 18 millimetres in diameter, and a negative one 15 millimetres in diameter, when the arc was respectively 4, 7 and 18 millimetres long. From the drawings it could be seen that using a *cored* positive carbon *diminishes* the visible part of the arc, and, when the arc is long, causes the central portion to become gourd-shaped.

The Applied Mathematics Department of University College showed a series of diagrams, calculated and prepared by Miss Alice Lee, to illustrate the time-decay of the field due to a Hertzian oscillator. The late Prof. Hertz prepared four diagrams to illustrate the nature of the field in the neighbourhood of an oscillator giving a stable wave train. His theory requires modification, owing to every Hertzian oscillator really giving a rapidly damped wave train. Miss Lee's diagrams illustrated the changes in the field during 6½ complete oscillations. Four systems of curves gave the points of the field with relative strengths 50, 30, 10 and 1. The decadence of the field was represented not only by the gradual change of shape of the curves, but by the complete disappearance of the curves of greater strength. When the series is complete, it is proposed to reduce it by photography and use it in a "wheel of life," to illustrate the decadence of an oscillator-field.

A curious model for showing the gyroscopic properties of a wheel was exhibited by Mr. Killingworth Hedges. The wheel was represented by a rim, having within it a heavy inner disc which could be made to revolve rapidly on the axis of the wheel. When the wheel was allowed to roll slowly down an inclined plane, and the inner disc was made to revolve in the same direction as the wheel, they both assisted to keep the system upright. When, however, the inner disc revolved in the opposite direction to the wheel, the system was in a state of unstable equilibrium which caused a rapid revolution through 180°, when both the wheel and the inner disc revolved in the same direction, and so produced a state of stable equilibrium.

Four photographic views taken by Mr. W. Bartier, and illustrating the accumulation of ice on the river near the Beckton Gas Works, North Woolwich, in February of this year, were shown by Mr. G. J. Symons.

Photographs of curvilinear crystals of water were exhibited by Dr. Gladstone, F.R.S. The photographs were taken during the severe frost of last February, and showed the forms assumed by the vapour when frozen upon a shop window, and the glass roof of a photographer's studio. All the lines of the crystals were curved. Another exhibit by Dr. Gladstone consisted of a blue photograph showing the way in which a solution of sodium salts mixed with some earthy matter and water may be made to crystallise on evaporation. This specimen showed many spiral forms. It, and the original specimens, were prepared by Mrs. M. Watts Hughes.

Prof. A. G. Greenhill and Mr. T. I. Dewar exhibited an algebraical spherical catenary. By a special choice of the constants, depending upon the quinquisection of the period of the associated elliptic functions, the general equations of the spherical catenary, considered by Clebsch in Crelle, 57 were shown reduced so as to make the projection of the chain on a horizontal plane a closed algebraical curve of the tenth degree.

A number of interesting Japanese pictures, selected to illustrate the effects of time on the pigments used by the old painters of Japan (A.D. 1322 to the early part of the 19th century), were exhibited by Mr. W. Gowland. The chief pigments used in these pictures were as follows:—Greens and blues: carbonates of copper. Permanent blue: the mineral *Lapis lazuli*. Reds: red oxide of iron, vermilion, carmine. Permanent white: levigated oyster-shells. Black: soot prepared from the oil of *Sesamum Indicum*.

Tropical American butterflies, selected to show the existence of common colour-types among species associated in the same areas, were exhibited by Mr. W. F. H. Blandford. The phenomenon (*Homœochromatism*) is observed chiefly among species of the sub-families *Danainæ* and *Heliconiinæ*, but frequently species of other sub-families conform to the prevailing colour-type. To a particular class of cases of colour-resemblance the term "mimicry" has been applied. The series shown comprised:—(1) Species of *Heliconius* associated in pairs, the colour-type varying with the distribution from north to south. (2) Species of different genera (*Tithorea* and *Heliconius*) associated in pairs, and sometimes mimicked by butterflies of other families. (3) Homœochromatic types from various districts represented by numerous species in different families, sub-families and genera.

Minutiæ in finger-prints formed the exhibit of Mr. Francis Galton. The exhibit furnished an illustration of the exceptional trustworthiness of the finger-print method in determining questions of identity. It demonstrated that in a case of twins, whose portraits, classificatory measures, and finger-print formulæ were closely alike, the finger-print minutiæ were quite different. A second exhibit of Mr. Galton's was the print of the hand of a child eighty-six days old. An enlargement of this print showed the development of the ridges at that early age.

Mr. B. Harrison exhibited Eolithic implements from the chalk plateau of Kent. The implements were found by the exhibitor in pits, dug under the auspices of the British Association. Stones were shown which were thought to bear evidence of use as tools, naturally of suitable shapes, but improved upon by chipping round the edges where required.

The Curator of the Maidstone Museum showed a series of nine photographs (with map, ground plan, and section) of a

supposed Roman Mithræum or Mithraic temple discovered on the east bank of the river Medway at Wouldham, near Maidstone. The temple, or "cave," was found by workmen while engaged in removing sand for ballast, and excavated under the superintendence of the exhibitor. It had apparently been built into the bank, standing east and west, measuring 40 feet in length and 20 feet in width. Numerous fragments of tiles, samian and other pottery, animal bones, and a coin of Constantinopolis were found in the *filling*, but no statuary or inscriptions. So far this "cave" is the only one found south of the river Tyne.

Mr. G. F. Scott Elliot had on view photographs and objects illustrating his recent expedition to Ruwenzori. The photographs showed characteristic trees and shrubs of Taru, view of Kagera River, and of Ruwenzori. The objects consisted of Wandorobbo costume, sword, quiver, fire-stick, and arrows; Uganda pottery, bark cloths, &c.; banana meal, &c., in form, ready for export.

Mrs. Ellis Rowan exhibited Australian wild flowers in water-colours. The examples were from Northern Queensland and Western Australia.

A letter and original manuscript of Emin Pasha's last Ornithological Journal formed an interesting exhibit by Sir William H. Flower. The objects were found by the officers of the Congo Free State, after Emin had been murdered by the Arabs at Kinena, on or about October 28, 1892.

A series of cultures of various forms of the bacteria which had been isolated from the river Thames, and then cultivated by the methods employed in the laboratory, formed Prof. Marshall Ward's exhibit. The bacteria were grouped in sections corresponding to the different types, and characterised by differences as to the pigment-production, temperature of growth, capacity of forming spores, behaviour in different media, sizes, shapes, and power of movement, &c. Some of them belonged to common species; others were rare, or unknown, and not classified.

An instrument for describing parabolas by means of a combined sliding and link motion was exhibited by the inventor, Mr. H. Thomson Lyon.

Sir David Salomons showed new forms of "top" slides for the lantern, selenite and hot-water slide heated electrically; and illustrated the behaviour of a glow lamp in the magnetic field, &c.

Mr. F. Enock exhibited a living aquatic hymenopterous insect, *Polynema natans* (Lubbock), *Caraphractus cinctus* (Haliday), described by him in these columns a few weeks ago. This minute and most beautiful Hymenopteron was observed by Sir John Lubbock swimming or flying under water, crawling about weed, &c. The *Mymarida* (Hal.) all oviposit in the eggs of other insects: *Polynema natans*, according to Ganin, having been bred from eggs of a dragon fly, *Æschna*. The smallest of this family, *Camptoptera papaveris*, is but one eighty-fifth of an inch in length.

The bone structure in the dentary bone of *Gomphognathus*, a South African reptile, was illustrated by one of Prof. Seeley's exhibits. The bone structure in this fossil, which is of Permian age, is not distinguishable from the bone structure of a mammal, in the arrangement of the haversian canals and the lacunæ. Prof. Seeley also showed vertical sections through the maxillary and mandibular teeth from the same skull. This exhibit consisted of three vertical sections of the skull of *Gomphognathus* taken at the hinder termination of the hard palate, showing the conical forms of the single roots to the molar teeth, the flat transverse crowns to the teeth, and the way in which the mandibular teeth are opposed to those in the skull.

A sacred bone trumpet, drum, and flute were exhibited by Dr. George Harley. The trumpet and tom-tom drum were from the temple of a Buddhist monastery in Thibet. They were made from the bones of priests, from their being supposed to be more religiously effectual. The trumpet when blown emits a rising and falling mournful wailing sound. The drum, when the knobs attached to its strings are rattled against the skins, gives a disagreeable harsh noise which is thought to drive the evil spirit out of the temple. The flute is a Carib Indian's, from Guiana, made from the tibia of a deer (*Coassus rufinus*). From it can be got the notes 1, 2, and 3, in the natural harmonic ratios of 6, 7, and 8, as in the French flageolet.

The following exhibits, with demonstrations by means of the electric lantern, took place in the meeting room of the Society.

Lantern slides, illustrating the ethnography of British New Guinea, by Prof. A. C. Haddon. The slides illustrated the physical characters of different tribes inhabiting British New Guinea, some of the occupations of the people, several kinds of dances, and the distribution of dance-masks. A series of dwellings from one end of the Protectorate to the other was shown, and two types of canoes. Finally, illustrations of the decorative art of various districts were thrown upon the screen. Evidence was given in support of the view that British New Guinea is inhabited by true dark Papuans, and by two distinct lighter Melanesian peoples, one of whom may have come from the New Hebrides, and the other from the Solomon Islands.

Dr. J. Joly exhibited examples of colour photography, and described his method of obtaining them. The photographs were a realisation of composite heliochromy in a single image. The method of composite heliochromy requires three images superimposed by projection. In Dr. Joly's photographs the colour analysis and synthesis are carried out in the one image. The colours are the natural colours as they registered themselves upon the plate, and in no case altered after reproduction. The specimens shown were first attempts, produced with rough apparatus. The images showed a slightly grained appearance, but this is avoidable with proper appliances. The process of taking and reproducing the photographs differs in no way from ordinary photography upon the dry plate, save that the sensitive plate is exposed in the camera behind a screen lined in particular colours. The positive is subsequently viewed through a screen lined with three other colours; the three "fundamental colours," which upon the three-colour theory of vision are supposed to give rise to all our colour sensations.

ON THE TEMPERATURE VARIATION OF THE THERMAL CONDUCTIVITY OF ROCKS.[1]

§ 1. THE experiments described in this communication were undertaken for the purpose of finding temperature variation of thermal conductivity of some of the more important rocks of the earth's crust.

§ 2. The method which we adopted was to measure, by aid of thermoelectric junctions, the temperatures at different points of a flux line in a solid, kept unequally heated by sources (positive and negative) applied to its surface, and maintained uniform for a sufficiently long time to cause the temperature to be as nearly constant at every point as we could arrange for. The shape of the solid and the thermal sources were arranged to cause the flux lines to be, as nearly as possible, parallel straight lines; so that, according to Fourier's elementary theory and definition of thermal conductivity, we should have

$$\frac{k(\mathrm{M},\ \mathrm{B})}{k(\mathrm{T},\ \mathrm{M})}=\frac{[v(\mathrm{M})-v(\mathrm{T})]\div\mathrm{MT}}{[v(\mathrm{B})-v(\mathrm{M})]\div\mathrm{BM}},$$

where T, M, B denote three points in a stream line (respectively next to the top, at the middle, and next to the bottom in the slabs and columns which we used); $v(\mathrm{T})$, $v(\mathrm{M})$, $v(\mathrm{B})$ denote the steady temperatures at these points; and $k(\mathrm{T},\ \mathrm{M})$, $k(\mathrm{M},\ \mathrm{B})$, the mean conductivities between T and M, and between M and B respectively.

§ 3. The rock experimented on in each case consisted of two equal and similar rectangular pieces, pressed with similar faces together. In one of these faces three straight parallel grooves are cut, just deep enough to allow the thermoelectric wires and junctions to be embedded in them, and no wider than to admit the wires and junctions (see diagram, § 8 below). Thus, when the two pieces of rock are pressed together, and when heat is so applied that the flux lines are parallel to the faces of the two parts, we had the same result, so far as thermal conduction is concerned, as if we had taken a single slab of the same size as the two together, with long fine perforations to receive the electric junctions. The compound slab was placed with the perforations horizontal, and their plane vertical. Its lower side, when thus placed, was immersed under a bath of tin, kept melted by a lamp below it. Its upper side was flooded over with mercury in our later experiments (§§ 6, 7, 8), as in Hopkins' experiments on the thermal conductivity of rock. Heat was carried off from the mercury by a measured quantity of cold water poured upon it once a minute, allowed to remain till the end of a minute, and then drawn off and immediately replaced

[1] A paper by Lord Kelvin, P.R.S., and J. R. Erskine Murray, read at the Royal Society on May 30.

by another equal quantity of cold water. The chief difficulty in respect to steadiness of temperature was the keeping of the gas lamp below the bath of melted tin uniform. If more experiments are to be made on the same plan, whether for rocks or metals, or other solids, it will, no doubt, be advisable to use an automatically regulated gas flame, keeping the temperature of the hot bath in which the lower face of the slab or column is immersed at as nearly constant a temperature as possible, and to arrange for a perfectly steady flow of cold water to carry away heat from the upper surface of the mercury resting on the upper side of the slab or column. It will also be advisable to avoid the complication of having the slab or column in two parts, when the material and the dimensions of the solid allow fine perforations to be bored through it, instead of the grooves which we found more readily made with the appliances available to us.

§ 4. Our first experiments were made on the slate slab, 25 cm. square and 5 cm. thick, in two halves, pressed together, each 25 cm. by 12·5, and 5 cm. thick. One of these parts cracked with a loud noise in an early experiment, with the lower face of the composite square resting on an iron plate heated by a powerful gas burner, and the upper face kept cool by ice in a metal vessel resting upon it. The experiment indicated, very decidedly, less conductivity in the hotter part below the middle than in the cooler part above the middle of the composite square slab. We supposed this might possibly be due to the crack, which we found to be horizontal and below the middle, and to be complete across the whole area of 12½ cm. by 5, across which the heat was conducted in that part of the composite slab, and to give rise to palpably imperfect fitting together of the solid above and below it. We therefore repeated the experiment with the composite slab turned upside down, so as to bring the crack in one half of it now to be above the middle, instead of below the middle, as at first. We still found, for the composite slab, less conductivity in the hot part below the middle than in the cool part above the middle. We inferred that, in respect to thermal conduction through slate across the natural cleavage planes, the thermal conductivity diminishes with increase of temperature.

§ 5. We next tried a composite square slab of sandstone of the same dimensions as the slate, and we found for it also decisive proof of diminution of thermal conductivity with increase of temperature. We were not troubled by any cracking of the sandstone, with its upper side kept cool by an ice-cold metal plate resting on it, and its lower side heated to probably as much as 300° or 400° C.

§ 6. After that we made a composite piece, of two small slate columns, each 3·5 cm. square and 6·2 cm. high, with natural cleavage planes vertical, pressed together with thermoelectric junctions as before; but with appliances (see § 10) for preventing loss or gain of heat across the vertical sides, which the smaller horizontal dimensions (7 cm., 3·5 cm.) might require, but which were manifestly unnecessary with the larger horizontal dimensions (25 cm., 25 cm.) of the slabs of slate and sandstone used in our former experiments. The thermal flux lines in the former experiments on slate were perpendicular to the natural cleavage planes, but now, with the thermal flux lines parallel to the cleavage planes, we still find the same result, smaller thermal conductivity at the higher temperatures. Numerical results will be stated in § 12 below.

§ 7. Our last experiments were made on a composite piece of Aberdeen granite, made up of two columns, each 6 cm. high and 7·6 cm. square, pressed together, with appliances similar to those described in § 6; and, as in all our previous experiments on slate and sandstone, we found less thermal conductivity at higher temperatures. The numerical results are given in § 12.

§ 8. The accompanying diagram (Fig. 1) represents the thermal appliances and thermoelectric arrangement of §§ 6, 7. The columns of slate or granite were placed on supports in a bath of melted tin with about 0·2 cm. of their lower ends immersed. The top of each column was kept cool by mercury, and water changed once a minute, as described in § 3 above, contained in a tank having the top of the stone column for its bottom, and completed by four vertical metal walls fitted into grooves in the stone, and made tight against wet mercury by marine glue.

§ 9. The temperatures v(B), v(M), v(T) of B, M, T, the hot, intermediate, and cool points in the stone, were determined by equalising to them successively the temperature of the mercury thermometer placed in the oil-tank, by aid of thermoelectric circuits and a galvanometer used to test equality of temperature by nullity of current through its coil when placed in the proper circuit, all as shown in the diagram. The steadiness of temperature in the stone was tested by keeping the temperature of the thermometer constant, and observing the galvanometer reading for current when the junction in the oil-tank and one or other of the three junctions in the stone were placed in circuit. We also helped ourselves to attaining constancy of temperature in the stone by observing the current through the galvanometer, due to differences of temperature between any two of the three junctions B, M, T placed in circuit with it.

§ 10. We made many experiments to test what appliances might be necessary to secure against gain or loss of heat by the stone across its vertical faces, and found that *kieselguhr*, loosely packed round the columns and contained by a metal case surrounding them at a distance of 2 cm. or 3 cm., prevented any appreciable disturbance due to this cause. This allowed us to feel sure that the thermal flux lines through the stone were very approximately parallel straight lines on all sides of the central line BMT.

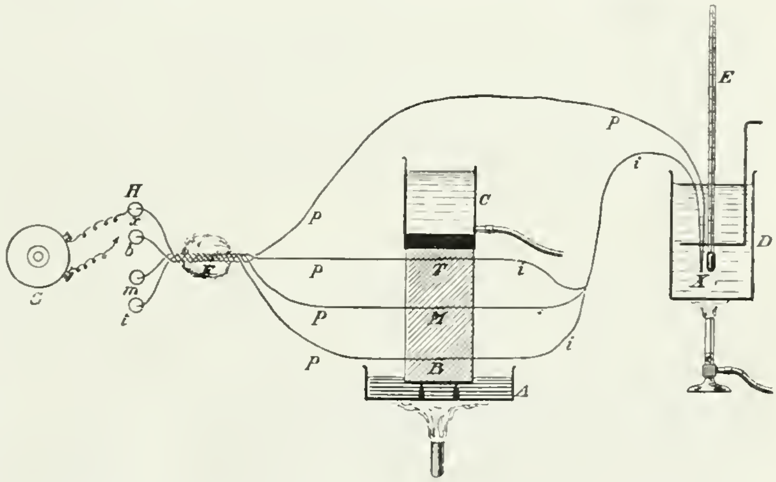


FIG. 1.—Iron wires are marked *i*. Platinoid wires are marked *p*. B, M, T. Thermoelectric junctions in slab. X. Thermoelectric junctions in oil bath. A. Bath of molten tin. C. Tank of cold water. D. Oil bath. E. Thermometer. F. Junctions of platinoid and copper wires. The wires are insulated from one another, and wrapped altogether in cotton wool at this part, to secure equality of temperature between these four junctions, in order that the current through the galvanometer shall depend solely on differences of temperature between whatever two of the four junctions, X, T, M, B, is put in circuit with the galvanometer. G. Galvanometer. H. Four mercury cups, for convenience in connecting the galvanometer to any pair of thermoelectric junctions. *x*, *b*, *m*, *t*, are connected, through copper and platinoid, with X, B, M, T, respectively.

§ 11. The thermometer which we used was one of Casella's (No. 64,168) with Kew certificate (No. 48,471) for temperature from 0° to 100°, and for equality in volume of the divisions above 100°. We standardised it by comparison with the constant volume air thermometer[1] of Dr. Bottomley with the following result. This is satisfactory as showing that when the zero error is corrected the greatest error of the mercury thermometer, which is at 211° C., is only 0·3°.

Reading.		
Air thermometer.	Mercury thermometer.	Correction to be subtracted from reading of mercury thermometer.
°	°	
0	1·9	1·9
120·2	122·2	2·0
166·8	168·6	1·8
211·1	212·7	1·6
265·7	267·5	1·8

[1] *Phil. Mag.*, August 1888, and *Roy. Soc. Edin. Proc.*, January 6, 1888.

§ 12. Each experiment on the slate and granite columns lasted about two hours from the first application of heat and cold: and we generally found that after the first hour we could keep the temperatures of the three junctions very nearly constant. Choosing a time of best constancy in our experiments on each of the two substances, slate and granite, we found the following results:—

Slate: flux lines parallel to cleavage.

$$\tau(T) = 50^\circ{\cdot}2 \text{ C.}$$
$$\tau(M) = 123^\circ{\cdot}3.$$
$$\tau(B) = 202^\circ{\cdot}3.$$

The distances between the junctions were BM = 2·57 cm. and MT = 2·6 cm. Hence by the formula of § 2.

$$\frac{k(M, B)}{k(T, M)} = \frac{73{\cdot}1 \div 2{\cdot}6}{79{\cdot}0 \div 2{\cdot}57} = \frac{28{\cdot}1}{30{\cdot}7} = 0{\cdot}91.$$

Aberdeen granite:

$$\tau(T) = 81^\circ{\cdot}1.$$
$$\tau(M) = 145^\circ{\cdot}6.$$
$$\tau(B) = 214^\circ{\cdot}6.$$

The distances between the junctions were BM = 1·9 cm. and MT = 2·0 cm.

$$\frac{k(MB)}{k(TM)} = \frac{64{\cdot}5 \div 2{\cdot}0}{69{\cdot}0 \div 1{\cdot}9} = \frac{32{\cdot}2}{36{\cdot}3} = 0{\cdot}88.$$

§ 13. Thus we see, that for slate, with lines of flux parallel to cleavage planes, the mean conductivity in the range from 123° C. to 202° C. is 91 per cent. of the mean conductivity in the range from 50° C. to 123° C., and for granite, the mean conductivity in the range from 145° C. to 214° C. is 88 per cent. of the mean conductivity in the range from 81° C. to 145° C. The general plan of apparatus, described above, which we have used only for comparing the conductivities at different temperatures, will, we believe, be found readily applicable to the determination of conductivities in absolute measure.

THE RELATION BETWEEN THE MOVEMENTS OF THE EYES AND THE MOVEMENTS OF THE HEAD.[1]

WE all know that it was a long time before mankind found out that the earth moves. For ages the apparent motion of the heavenly bodies was supposed to be their real motion, the earth being fixed. We, who know something of the truth in this matter, do not, however, any more than our ancestors did, see or feel the earth move. We believe that it does so either because we have been told by some one who, we think, knows about such things, or because we have reasoned the matter out from data observed by ourselves or reported by credible observers. But in habitual thought and speech we go back to the old assumption which, for our practical, terrestrial purposes, answers well enough, and is perfectly in accordance with our sensations.

When we turn from the great Cosmos to the microcosm: when we compare the motion of our own body among the various fixed (terrestrially fixed) and moving bodies around us, with the motion of the earth among the stars, we find quite a different state of matters. It never occurs to us that our own body is at rest, and that the trees, houses, &c., move. When we really move we not only know, but feel and see that we are moving, and every one learned or ignorant, old or young—if only he is sober—feels and sees that the solid earth is fixed, except on the rare occasion of an earthquake, and in the case of some illusions which we shall have to consider. I wish to discuss the cause of this *sensation* of the fixedness of the earth, and also incidentally of the exception implied in the words I have just used, "if only he is sober."

If we keep our head fixed and look at any really fixed scene—say, a room in which there is nothing moving—or a landscape, if we can find one without railway trains, ships, moving beasts, or flying birds, we can allow our eyes to run over it in as uniform or as irregular a way as we please, and see that the scene remains fixed. We might have supposed that, as we move our eyes from right to left the whole scene, like a moving panorama, would seem to move from left to right, but it does not do so. It remains visibly at rest, and we know, without any reasoning about it, that the changes of view were produced by the motion of our eyes.

We fancy that we can move our eyes uniformly, that by a continuous motion like that of a telescope we can move our eyes along the sky-line in the landscape or the cornice of the room, but we are wrong in this. However determinedly we try to do so, what actually happens is, that our eyes move like the seconds hand of a watch, a jerk and a little pause, another jerk and so on; only our eyes are not so regular, the jerks are sometimes of greater, sometimes of less, angular amount, and the pauses vary in duration, although, unless we make an effort, they are always short. During the jerks we practically do not see at all, so that we have before us not a moving panorama, but a series of fixed pictures of the same fixed things, which succeed one another rapidly. It is not difficult to understand how this gives rise to a sensation of the fixedness of the external scene. If, in the otherwise fixed scene, there is a really moving object, we see it move, because during the pauses, short as they are, the moving object has visibly changed its place, and in each of our fixed pictures the moving object is seen to move. If it moves too slowly for this, then we do not *see* it move, but only infer its motion from comparison of its position at different times. If we keep our eyes fixed on the moving object, and this is possible if it does not move too fast or too irregularly, then we see it fixed and the really fixed things moving, an illusion we have all observed when the pier seems to move and the steamer remain at rest.

That the eyes jerk in the way now stated can be made plain by means of a simple experiment. If we have in the field of view a bright object, such as an incandescent electric lamp, and after running our eyes over the scene before us, shut our eyes, we see secondary images of the bright object.[1] Now if the eyes move continuously from one position to another, we should see between the two secondary images of the bright object corresponding to these two positions, a bright band composed of an infinite number of images each infinitely near its two neighbours. But we see no such band, but a finite number of sharp individual images, each of which corresponds to the position of the eyes during a pause between jerks; unless the bright object is very bright, there is nothing in the secondary image to represent the positions of the eyes during the jerk. If for a bright object we take the sun, then we do see bands joining the sharp secondary images. These bands are fainter than the sharp images, and die away sooner. They are the impressions made on the retina by the image of the sun passing rapidly across it during the jerk. But, if with the fixed bright object in the field we follow with our eyes a really moving thing, then on shutting the eyes we see a band of light, because the image of the bright object passed not very rapidly across the retina.

This habit of jerking the eyes from one position of vision to another, as fast as the light, well-poised globes can be swung round by the quick-working, straight-fibred muscles which move them, may be an innate habit, or it may have been acquired by our looking at things and turning quickly from one object of interest to another: at all events, it is now the way in which alone we can move them, unless we fix them on a moving object.

So far I have supposed the head fixed and the eyes alone moving. Let us now attend to what happens when we move our head.[2]

The movement of the head, unless it is very rapid, makes no difference at all in the phenomena just described.

If we call the line along which we look during the pause between the two jerks a glance-line, we may describe the whole phenomenon by saying that the glance-lines are fixed relatively to fixed external objects, whether the head is rotated or not. This, of course, means that, during a pause, the eyes are rotated relatively to the head about the axis about which the head is really rotated, in the opposite sense and through the same angle as the head.

It might, for all that has been yet said, be supposed that this fixedness of the glance-lines, when the head is rotated, depends on the habit of looking at things; but that this is not the cause, or, at all events, not the only cause, is plain from the fact that the same relative movements of the eyes take place when we

[1] Being the Fourth "Robert Boyle" Lecture, delivered before the Oxford University Junior Scientific Club, at the University Museum, Oxford, on May [illegible], by Prof. A. Crum Brown, F.R.S.

[1] The secondary images are better seen if we look at a white surface and wink rapidly.

[2] By "moving the head," I mean moving the head either alone or along with the body or any part of it.

look at an objectless field of view, such as the clear, cloudless sky, or, as was, I believe, first noticed by Dr. Breuer, when the eyes are shut. By placing the fingers lightly over the closed eyelids we can feel the motion of the prominent cornea. If, with eyes shut and fingers so placed on the eyelids, we turn the head or turn head and body round, we feel the eyes twitch. As the head turns round the eyes retain for a little a fixed orientation in respect to external fixed things, and then jerk so as to make up for lost time, again pause, and again jerk, and so on. So that while the head turns uniformly, the eyes, which must, of course, on the whole make one full turn, while the head makes one full turn, do their rotation intermittently, being, so to speak, left behind by the head, and then making up by a rapid jerk.

Another proof that these compensatory movements, as they may be called, of the eyeballs are not, or, at least, not wholly, caused by the effort of looking at things, is afforded by observing what happens when the head is rotated about a fore and aft axis, about an axis coinciding with a glance-line. If we keep our eyes fixed on a particular point and rotate the head about the line along which we look,[1] we still see things fixed, the world does not seem to revolve about our fore and aft axis. Here also we can show by means of secondary images that we see a series of fixed pictures.

If, with a bright object in the field of vision, we fix our eyes and keep them fixed on a point, about 15° distant from the bright object (if we keep both eyes open, about as far from our eyes as the bright object is, so as to avoid double vision), and then rotate the head about a fore and aft axis through, say, 30° by inclining the head towards one shoulder, and shut the eyes after this performance, we see a number of sharp secondary images of the bright object arranged upon an arc of a circle, the radius of which is the angular distance of the bright object from the point fixed.

If I have rotated my head through about 30°, I see about five secondary images, so that what I call the *angle of rotatory nystagmus* is, in my case, about 6°. Here we have been looking all the time at the same point, and it is not easy to suppose that the very slight attention we pay to objects seen indirectly, or, as we sometimes say, "with the tail of the eye," could lead to a habit, so fixed that we cannot escape it, of moving the eyeballs in the way described.

I have said that the movement of the head, *unless it is very rapid*, does not affect the fixedness of the glance-lines. Translatory motion of our body may be so rapid, as in a railway train, that the eyes cannot twitch so fast as to keep the glance-lines fixed relatively to near fixed objects.

The eyes do their best, they twitch but not enough, unless the train is moving slowly, and near objects seem to fly backwards. We succeed with fixed objects at a greater distance from us; we can see them fixed, and all objects between us and such visibly fixed objects are seen to move backwards, fixed things beyond them seem to move forward with us. Of course if, by keeping our attention on our carriage and its contents, our glance-lines become fixed in reference to these really moving things, they seem fixed, and the whole world outside of the carriage is seen to move in the direction opposite to that of our real motion. It is also obvious that rotation of the head, if it is more rapid than the quickest possible rotation of the eyeball in the head, must affect the position of a glance-line, for, in order that the glance-line may remain fixed, the eyeball must rotate in reference to the head as fast in one sense as the head rotates in reference to external things in the other sense; but in the case supposed, the eyeball cannot do so. We can try this experiment without having recourse to mechanical means of rotating our body and head, which, of course, we could do as fast as we please, and a great deal faster than would be either pleasant or safe. The most rapid rotation of our head which we can produce by the direct action of our muscles is what is known as wagging, that is, a rotation about a vertical axis upon the joint between the first two vertebræ. In this way we can give the head an angular velocity considerably greater than the maximum angular velocity of the eyeball. When we do this as fast as we can, we see that external things do not appear steady. When we wag our head to the right we see the world wag to the left, and *vice versa*. But the external really fixed things do not appear to us to describe nearly so large an angle as the head really does, the eyes make an effort to compensate the rotation of the head, an effort only partially successful, the angle through which external things seem to move being the difference between the actual angular rate of movement of the head, and the maximum possible angular rate of movement of the eyeball in its socket. This difference can best be observed and, indeed, can be approximately measured by observing a distant light on a dark night, while we wag the head. The point of light seems drawn out into a horizontal line of light, the apparent length of which is the angular difference in question. As we can wag our head much faster than we can nod it, the apparent length of the vertical line of light into which a bright point is drawn out when we look at it and nod as rapidly as we can, is much less than that of the horizontal line of light just spoken of: but I find that I can, by nodding, rotate my head about a right and left axis a little faster than I can rotate my eyes about the same axis, so that the luminous point does appear drawn out into a short vertical line.

Such violent movements of the head occur sometimes in our ordinary (not experimental) use of our eyes, but they are rare and isolated, so that the disturbance of the fixedness of the glance-lines which they cause does not really affect our sense of the fixedness of the world. The illusion of the moving pier and fixed steamer, which we have all also observed when there is a train alongside that in which we happen to be, and we see the moving train fixed and the fixed train moving, is corrected by looking at the shore or the railway station. For a moment these also seem to move, but our glance-lines almost instantly become fixed in reference to these things which we know are fixed, and it is then difficult to recall the illusion. Another similar case is that of the moon and the clouds. We sometimes see the moon moving and the clouds fixed, sometimes the clouds moving and the moon fixed, as our glance-lines are fixed relatively to the clouds or to the moon, and a little practice enables us to change from the one sensation to the other at will.

What has been said seems to show that our immediate sense that the earth and what we call fixed objects on it are fixed is a consequence of the way in which we move our eyes, and, in particular, of the way in which, by a suitable movement of the eyeballs, we involuntarily and unconsciously compensate movements of the head, voluntary or involuntary, conscious or unconscious.[1]

That such an immediate sense of the fixedness of external fixed things is of great use to us in moving about among them is plainly shown when we observe the trouble which a drunken man, who has lost this sense, has in guiding himself.

I now turn to the question. What is the cause of this prompt and wonderfully accurate compensatory movement of the eyeballs?

There are three sources from which we can obtain information leading to an answer. (1) Experiments on ourselves, (2) anatomical observations and measurements, and (3) observations of the effects of injuries to the labyrinth of the internal ear.

I shall consider these in their order.

By experiments on ourselves I mean the study of the effect on the motion of the eyes and on our sense of the fixedness of external things, of movements of our head (in this case, always along with the rest of our body) which we do not make, as a rule, for any other purpose.

I have already stated that if we shut our eyes, place our fingers on the eyelids, and turn round about a vertical axis, we feel with our fingers the jerking motion of the eyeballs. If instead of turning once round, we turn round several times, still better if we seat ourselves on a turning-table and get some one else to turn it and us round at a uniform rate, we find that the jerks become less and less frequent, and after two or three turns cease altogether. Another thing which we observe is, that although the turn-table is being turned round at a perfectly uniform rate, we feel the rotation becoming slower and slower, and when the jerks of the eyeballs have quite ceased we feel ourselves at rest, and have no sensation of rotation. Let us for convenience call the sense in which the rotation is still going on positive. This uniform positive rotation has become to us imperceptible (as long as we keep our head in the same position in respect to the vertical), and is what we may call a new zero of rotation. If the rate of rotation is now increased, we feel this increase as a positive rotation; if it is diminished, we feel the diminution as a negative

[1] If we take a sufficiently distant object as the thing to be looked at, we may neglect the want of coincidence of the two glance-lines belonging to the two eyes, and, moreover, all that is here described is seen as well, though not so conveniently with one eye shut.

[1] I need hardly repeat that, by movements of the head, I mean movements of the head whether accompanied or not by movements of the body.

rotation—a rotation the other way about. What we really perceive then is *acceleration* of rotation, using the word acceleration in its technical sense. If the turn-table is stopped, this is a negative acceleration, and what we feel is that we are being turned round in a negative sense, and at the same time we feel our eyeballs jerk. The sense of rotation and the jerking die away in this as in the former case.

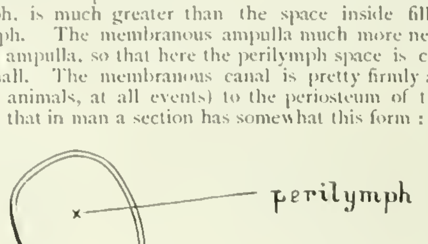
If, while we are being turned round with uniform angular velocity, but after all sense of rotation and all jerking of the eyeballs have ceased, we open our eyes, we still feel ourselves quite at rest, but we see all external objects turning round us; as has been well said by Prof. Mach, the external world seems to turn round inside an outer unseen fixed world. It is in reference to this imaginary fixed world that our glance-lines are now fixed. If the rate of rotation is changed while the eyes are open, the sensation of rotation is exactly the same as if they were shut, we feel the acceleration—positive or negative—as a rotation in the one or in the other sense, and the jerks of the eyeballs take place as if the real external world were not there, and we were looking beyond it at the unseen fixed world outside of it, that imaginary world in reference to which our glance-lines are now fixed.

If while the experiment I have described is going on, we move so as to change the direction, in our head, of the axis of rotation—for instance, if, after uniform rotation about a vertical axis has gone on, with the head in its usual upright position, until the sense of rotation has ceased, we bow our head forwards so that the axis of rotation is now parallel to a line from the occiput to the chin, a very striking, and somewhat alarming, but most instructive sensation is experienced. What we feel is that we are being turned round with a rotation which is the resultant of two rotations of equal angular velocity—one the real rotation about what is now the vertical, the other the imaginary (but equally perceived) rotation in the opposite sense about the line in the head which was vertical. If the angular movement of the head is small, so that the angle between what is the vertical and what was the vertical is small, then the two component rotations nearly neutralise one another, and the strange and alarming resultant is slight; but if the head is bent so that the old and new verticals are at right angles to one another, the real and the imaginary components are both felt in full, and the effect is very startling. If the rate of rotation is changed simultaneously with the change of position of the head, we have a resultant of two rotations of different angular velocity. The most easily observed case of this kind is when the rotation is stopped altogether at the moment of change of position of the head. Here the real component is zero, and we have only the imaginary one. This is the case of the well-known practical joke: a man is asked to plant the poker before him on the floor, place his forehead on the end of it, walk round it three times, and then rise and walk to the door. The preliminary part of this experiment presents no difficulty: the victim plants the poker, puts his forehead on it, walks round it with the greatest ease and with no sense of anything unusual. But when he rises, the line in his head which was vertical is now horizontal, and he feels himself turned round about that horizontal line. The external world he also sees turning round this line, objects on the one side rising up and objects on the other side sinking down. In this visibly swaying world he has to guide his sensibly rotating body, and if his friends do not catch hold of him he is pretty sure to fall. All these experiments are most conveniently made on a smoothly working turn-table of such a size that one can comfortably lie down upon it. By the kindness of Messrs. Dove, lighthouse engineers, I had the use of a large turn-table made for the revolving lantern of a lighthouse. It could be turned round smoothly and uniformly, at the moderate speed that is most suitable for experiments of the kind in question. A few experiments with such an apparatus will convince any one that we have here to do with a perfectly definite sense, and not with any vague sensations caused by the inertia of the soft parts of the body.

This is one of the ways in which the phenomena have been explained by those who hesitate to believe that there can be a definite special sense only discovered within the last few years. That the origin of the sensation is not in the soft parts of the body generally, but in the head, is made perfectly plain by the fact that the position of the head and the changes of that position alone determine the sensations. We must therefore look in the head for the organ of this sense.

In close proximity to the cochlea, which is universally regarded as the organ of hearing, there is an organ of very striking, and we might say mysterious, form. It occurs in all vertebrates, and occurs in them fully developed, except in the lowest forms of fish. It is contained in a bony or cartilaginous cavity, which communicates with the cochlea or lagena. This cavity may be divided into the vestibule and the three semicircular canals. The canals open at both ends into the vestibule, and each has at one end an enlargement called the ampulla.[1] Within this bony case is contained a membranous structure, consisting of the utricle, situated in the vestibule, and three membranous canals, each in one of the bony canals, each with an ampulla in the bony ampulla, and each opening at both ends into the utricle. The vestibule contains, besides the utricle, the saccule, a membranous bag continuous with the cochlear duct, and has in the side next the tympanic cavity a hole in the bony wall filled in by a membrane, and known as the *fenestra ovalis*. The saccule and the utricle have each a spot on the lower wall supplied with nerves ending in hair-cells, and known as the *macula acustica*.

The *maculæ acusticæ* are probably, as suggested by Mach and Breuer, organs fitted to perceive acceleration of translatory motion, and are not connected directly with the function of the semicircular canals. The *fenestra ovalis* belongs to the organ of hearing, which may thus be said to have a right of way through the vestibule. We need not therefore here consider any further these organs, but confine ourselves to the semicircular canals and the utricle in its relation to them. As already stated, each bony canal contains a membranous canal. The membranous canal is, except at the ampulla, much smaller in bore than the bony canal, so that the space outside the membranous canal filled with perilymph, is much greater than the space inside filled with endolymph. The membranous ampulla much more nearly fills the bony ampulla, so that here the perilymph space is comparatively small. The membranous canal is pretty firmly attached (in some animals, at all events) to the periosteum of the bony canal, so that in man a section has somewhat this form:



Each canal is, in all animals I have examined, approximately in a plane, and it is important to consider the relations of these planes to one another and to the mesial plane of the head.

As I have brought part of the apparatus with me, I may shortly describe the method I used to measure the angles which these planes make with one another, and also an improved method, of which I have not yet had time to make any very full trial.

[The method illustrated by the human skull shown is fully described, with woodcuts from photographs, in Prof. McKendrick's "Text-book of Physiology," vol. ii. pp. 697–699, and therefore need not be reprinted here. The other method will, I hope, give more accurate measurements.]

It consists in attaching the preparation—either a cast of the canals, or, in the case of a bird, the dissected and cleaned bony canals—to one arm of a branched rod, and a lump of wax to the other. The rod is then fixed to the large apparatus already referred to. The canals are successively made horizontal, and a small plate of glass fixed horizontally in each case—parallel therefore to each canal—to the lump of wax. We can also attach a glass plate parallel to the mesial plane. We can thus have, on a comparatively small piece of wax, glass plates parallel to all the planes, the relations of which to one another are to be measured. The lump of wax is then removed from the rod, and the angles between the planes of the glass plates measured by means of an ordinary reflexion goniometer.

The general results are:

(1) The canals do not lie rigorously in planes, but sufficiently nearly so to give closely accordant results.

(2) The external canals are very nearly at right angles to the mesial plane, and therefore, from the bilateral symmetry, the two external canals are very nearly in one plane.

(3) The superior and posterior canals of the same side make

[1] In all animals the non-ampullary ends of the superior and the posterior canal have a common opening into the vestibule.

approximately equal angles with the mesial plane. In all cases which I have examined, the angle between the posterior canal and the mesial plane is somewhat larger than that between the superior canal and the mesial plane.

From the bilateral symmetry, therefore, the superior canal of the one side is nearly, but not quite, parallel to the posterior canal of the other side. In the discussion of the way in which the system of canals may be supposed to act, I shall for convenience assume that these canals are parallel, as the deviation from exact parallelism only complicates, but does not at all vitiate, the argument.

(4) In man, and in a large number of other animals, the three canals are very nearly at right angles to one another. But, in a good many of the animals I have looked at, the superior and posterior canals make with one another an angle considerably greater than a right angle.

Looking at the six canals as forming one system, we see that we have three axes, that at right angles to each axis there are two canals, one in the one internal ear, the other in the other; these two canals having their ampullæ at opposite ends, so that if rotation takes place about the axis, the ampulla in the one case precedes the canal, in the other follows it. The vertical axis, as we may call that at right angles to the two external (or horizontal) canals, is pretty nearly vertical in most animals, in the usual position of the head when the animal looks to the horizon; in man it is not exactly so, we must bow our head a little to make this axis vertical. If we suppose we are looking north, the other two axes are north-east and south-west and north-west and south-east respectively. In man they pass from the eye of one side to the mastoid process of the other side, and are nearly at right angles to one another. As already stated, in some animals they are inclined and are nearer the right and left than the fore and aft line in the head.

In order to see how such a system can work as a hydrodynamical instrument, let us first consider one canal.

Here we have two watery liquids, the endolymph within the membranous canal, its ampulla and the utricle, the perilymph between these and the bony case. How will these behave when rotation takes place about an axis normal to the plane of the canal? The inertia of the liquids will tend to produce a flow through the canal in the sense opposite to that of the rotation.

Let the rotation take place so that the ampulla precedes the canal. Here the endolymph will tend to flow from the utricle into the ampulla, and thence through the canal to the utricle again. But, as Mach has pointed out, the canal has too small a bore to allow of any sensible flow through it, so that the effect of this rotation will be to increase the pressure within the membranous ampulla. But (and this is a point to which, as far as I know, no one has hitherto called attention) as there will also be a tendency of the perilymph to circulate, so in its circle there is also a narrow place, namely at the ampulla; for as the membranous ampulla nearly fills its bony case, there is not much room there for the perilymph to pass from the vestibule into the space surrounding the membranous canal. There will, therefore, be a diminution of pressure of perilymph at the ampullary end of the canal, so that the ampullary walls will be stretched by the increase of pressure within and the diminution of pressure without. Of course when the rotation is kept up uniformly for some time the pressure inside and outside of the membranous ampulla is soon equalised, and the stretching or relaxation ceases. With the cessation of the stretching the sensation must also cease.

If now the rotation is stopped the perilymph and endolymph will tend to move on, and pressure will be produced inside the membranous ampulla of that canal, which during the rotation moved with ampulla following the canal.

All this will of course be reversed when the rotation takes place with the ampulla following the canal; the pressure inside the membranous ampulla will be diminished, that without increased, and the walls will become flaccid.

In each membranous ampulla there is a so-called *crista acustica* where nerves terminate in hair-cells, and it is not difficult to suppose that stretching of the ampullary walls will irritate these nerve-endings, while a relaxation of the ampullary walls will produce no irritation. If this be so, then we have three axes each with an organ sensitive to rotation about it in either sense, and capable of discriminating between the two; and as every rotation of the head can be resolved into component rotations about these three axes, we have the means of perceiving the axis and what we may call the intensity of the rotation, or perhaps more correctly the rotational acceleration.

This hydrokinetic theory of the function of the semicircular canals was propounded at very nearly the same time by Prof. Mach of Prague, Dr. Breuer of Vienna, and myself. I give the names in the order of publication. The views expressed by us were not exactly the same, and the statement of the theory I have just given is any one of them with additions and corrections from the other two.

I have not thought it necessary to refer to the hydrostatic theory of Goltz, or, indeed, to give any details of the literature of the subject. A very full and accurate digest of almost every thing that has been written on the functions of the several parts of the labyrinth of the ear has been published in Russian by Dr. Stanislaus von Stein, and translated into German by Dr. C. von Krzywicki.

The theory as I have just described it might perhaps have been developed, as I have here developed it, from a consideration of the structure and position of the canals. But, as a matter of fact, this was not the historical order. It was the experiments of Flourens that first directed attention to these organs as having something to do with the equilibrium of the body.

In reference to these experiments and those made since by many able physiologists and skilled operators, I shall only say that the results seem to me to be consistent with the hydrokinetic theory. Certain of de Cyon's experiments, in which he increased the pressure in the canals by inserting in them small tangle plugs without producing any nystagmus or rotatory movements of the head, appear to contradict the theory. But increase of pressure in the bony canal can have no tendency to stretch the walls of the membranous ampulla, and therefore could not be expected, if the theory as I have stated it is correct, to produce a sensation of rotation; what is required, is that the pressure inside the membranous ampulla should be greater than that outside of it.

The symptoms observed in cases of disease of the internal ear also appear to support this hydrokinetic theory.

But the position of the canals in close anatomical relation to the organ of hearing had impressed on the minds of physiologists so obstinate an opinion that they must be connected with the perception of sound in some way or other, that even now many will not admit that they are the peripheral organs of a sense of rotation.

A favourite theory was (and there are still some who hold it) that the semicircular canals give us information as to the direction in which sound comes to us. There are two ways in which we can show that this view is erroneous.

(1) By considering the physical conditions.

The shortest sound wave which we can hear is so long compared with the dimension of the ear, that every part of the ear must be at any instant in the same phase of the wave. We must assume that, as far as the effect of such sound waves is concerned, the liquid contents of the internal ear are incompressible. It is as absurd to speak of sound-waves travelling round one of the canals as to say that it is high water at one end of a dock and low water at the other, at the same time.

(2) By experiments on the way in which we really do perceive the direction of sound. I shall describe two such experiments. (*a*) Let the observer close his eyes—for security it is best to bandage them—seat himself in a chair, and keep his head steady. Now let an assistant produce a sharp short sound. In showing this experiment to Section D of the British Association, at its meeting at Belfast in 1874, I used three coins in the way I show you now. The observer can tell with really astonishing accuracy whether the sound comes from the right or from the left, because he hears it louder in the nearer ear, but he is without any knowledge at all as to whether it comes from above or below, from the front or the back. He forms a judgment indeed on this point, but his judgment is usually wrong, often very ludicrously so.

The experiment is most striking when the click is produced in the mesial plane of his head, in which case he has not the binaural effect to help him. In this connection I may say that I know no experiment which illustrates so well the marvellous delicacy of our sense of relative loudness of sound, a very small deviation from the mesial plane being quite certainly recognised.

We have then with one ear no means of ascertaining the direction of sound if we keep the head fixed. How then do we ascertain the direction of sound? for we all know that we

can do so with very considerable accuracy. This leads me to the second experiment. (*b*) Let the observer, still with eyes closed and bandaged, stand up and be at liberty to move his head. Let the assistant produce the clicking sound, not once only, but again and again at short intervals, always in the same place. The observer turns round until he faces the source of sound. He knows that he is facing it when he hears it equally loud in both ears, and hears it to the right when he turns a little to the left, and to the left when he turns a little to the right, that is the criterion of whether the source is behind or before him. Having now got the azimuth, he seeks the altitude. Moving his head about a right and left axis, he seeks the position in which he hears the sound best. He is now looking towards the source of the sound.

The concha of the external ear acts as a screen, and it is remarkable how much difference there is in the quality as well as in the loudness of most sounds with different altitudes.

Stand in front of a pipe from which water is rushing, and move the head round a right and left axis, bow, in fact, to the pipe, and a striking difference in the quality and loudness of the sound will be observed in the different positions of the head.

It may be said birds have no concha, and yet they perceive as well as we do the direction of sound. But there is a method by which, without any use of the action of the concha, and by purely binaural observations, we can ascertain the direction of sound. By one observation, as already described, we can find a plane containing the line along which the sound reaches us. That plane is at right angles to the line joining our two ears. By moving the head we can shift the line joining our two ears, and then by another similar observation obtain the plane at right angles to the new position of the line joining the two ears and containing the direction of sound. The direction of sound is the intersection of these two planes.

I do not think *we* use this method (although I have tried it and found it work), but we often see birds incline their heads when listening in such a way as to suggest that they use it.

There is another objection which is often brought against the theory I have been explaining. It is said, "Is it conceivable that there should be a special sense, common to man and all vertebrate animals, which has remained unknown till about twenty-two years ago? This is a sense invented, not discovered by scientific men, otherwise we should all have known about its existence at least."

This objection is not one to be met by contempt: it has a real basis, and as I believe this sense to be a real one, I feel bound to look for the cause of the incredulity.

A special sense is popularly understood to be a gateway of knowledge. Information as to external things comes to us in various ways, and each of these ways has from ancient time been recognised and named as a special sense. But this is not exactly the physiological way of looking at things. I may illustrate the difference by a sort of analogy. In a large business establishment the manager sits in his room upstairs. He has various ways of getting information. The post brings him letters, he looks at them; some he carefully considers and answers, others he looks at and puts into the waste-paper basket—but he has looked at them all. So we *see* things; many of the things we consider, take note of, others we pay no attention to—do not an hour later remember anything about them. But there are many messages which come to the business establishment and never reach the manager's room at all. They are attended to by clerks in the office. They are not futile, they are real messages and serve their purpose, a purpose essential to the carrying on of the business. If these were not attended to downstairs, the manager would very soon hear of it. So with us. There are what we may call sensory impressions which do not make their way to the conscious *Ego*, but are all the same properly attended to by what in us corresponds to the clerks. If our clerks neglect their work, the conscious *Ego* very soon becomes aware that there is something wrong.

In the case of the sense of rotation, ordinarily we pay no attention to its messages; the clerks at the sensory centres of the ampullary nerves, and at the motor centres of the muscles of the eyeballs, do all that is necessary. We perceive the result of their work in our visual sense of the fixedness of the outside world, and we do not trouble ourselves as to how the office work has been done.

But—and here I come to a matter I referred to early in this lecture—the office work is sometimes not well done, and the visual sense of the fixedness of the outside world is lost. If this is due to disease, we send for the doctor and ask him to find out what is wrong in the office, and, if he can, put it right. But there is a far more common cause of the loss of the visual sense of the fixedness of the outside world, one which it has not been left for two or three scientific men to discover in the last quarter of the nineteenth century. The most characteristic effect of alcohol is to make all reflex actions sluggish. Under the influence of a moderate dose of alcohol, what I have called the office work, goes on all right but not quite so fast as with no alcohol. The message arrives, and the answer is sent, but not quite so promptly. The conscious *Ego* may not note anything wrong, but a quantity of alcohol, far short of a dangerously poisonous dose, may delay the transmission of the signal to the muscles of the eyeball so much as to affect quite perceptibly the compensation of the movements of the head. A perfectly sober man sees the world wag a little when he wags his head very vigorously—a point of light is perceptibly drawn out into a horizontal line of light—the office work fails a little under such extreme pressure. But a little alcohol makes the office work fail more readily, and as the dose is increased it fails altogether, and the sense of the fixedness of the world is wholly lost. Even in such an extreme case of intoxication, short of paralysis, the drunken man may see the world steady, if only he can keep himself steady. I dare say we have all seen very drunken men walking quite straight, but with a preternatural fixedness of the head. If anything makes them move their head, they totter and reel. They move the head a little; that happens to them in consequence of a small and slow rotation of the head, which happens to us when we wag our head violently, and they reel and stagger just as we should reel and stagger if we tried to walk, violently wagging our head all the time.

Just as there are blind men and deaf men, so there are men who have lost or never had the sense of rotation. Such persons are almost always deaf-mutes. The close anatomical relation of the organ of hearing and the organ of the sense of rotation has this effect, that imperfect development of pathological injury of the one is usually associated with similar defect in the other. And experiments on deaf-mutes have shown that a large proportion of them are defective in the sense of rotation. This is shown by the absence of the normal jerking of the eyeballs when they are rotated, and by a perceptible insecurity in their gait. They do not reel as drunken men do, just as blind men find their way about much better than we could do if our eyes were bandaged up; they have learned to get on fairly well with the help of experience and their other senses.

I am not sure whether in this account of the sense of rotation, of its organ, and of the use of it, I have carried all my hearers with me, and convinced you of the real existence and real practical use of this sense. I hope, however, I have made it clear that the subject is worthy of attention, and that we have here matter for the careful consideration of physicists, physiologists, and psychologists.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—In a Convocation, held on Tuesday last, the University, or at least a section of it, displayed itself in an unfavourable light. The Convocation House was crowded, not because of the Statute on Research Degrees, which came before the House, and passed its final stage without opposition, but because of the proposal, which seemed to be a modest one, that Anthropology should be included among the subjects of the Final School of Natural Science, not as an extra, but as an equivalent subject. This proposal was from the first strongly opposed by a few members of Congregation, but passed the two readings in that body by substantial majorities. The opponents of the subject, however, were not content to accept the results of these votes, and issued an urgent whip to members of Convocation, with the result that the statute was rejected by 68 votes against 60. Presumably the philosophers, historians, and divines who succeeded in throwing out the statute at its final stage are pleased with their performance. To the outside world, which is less than ever convinced that education is comprised within the limits of the subjects of the School of Literae Humaniores, their action will be but another instance of the incompetency of a section of the classical world to understand what is going on around them. The circular which was issued

by the opponents of the statute was so artfully worded as to rouse theological suspicions. Reference was made to the undesirability of the comparative study of religions, and it was obvious that a considerable proportion of those who attended to vote against the measure, had come in obedience to a summons to resist the enemy, and were in no way qualified to form a judgment on educational matters. The larger proportion, however, consisted of those classical teachers whose belief it is that science may safely be ignored in a nineteenth century education, and that a "good general education" means only a training in the Greek and Latin languages, with a smattering of ancient history and philosophy. The result of the vote was a great disappointment to those who had hoped that the work of Prof. Tylor, Prof. Arthur Thomson, and Mr. H. Balfour, would find its fruition in a small but earnest school of anthropologists in Oxford.

The National Association for the Promotion of Technical and Secondary Education has made arrangements for a Conference of the representatives of Technical Education Committees to be held at the Royal United Service Institution, on July 11, when the Duke of Devonshire, President of the Association, will take the chair. The object of this Conference is to discuss means whereby the various authorities charged with the provision of technical education may be brought into closer relationship, and may be enabled to avail themselves of the results of the experience of others as regards many important details of their work. Among the subjects which it is proposed to deal with are (*a*) scholarships (local conditions and uniformity in respect to award and tenure), (*b*) evening continuation schools (the co-ordination of their work with that of evening science, art, and technical classes), (*c*) trade and technology classes and their relation to the various trades.

The chemical and engineering societies formed by the members of many of our polytechnic institutes might emulate, with advantage, the Engineering Society of the School of Practical Science, Toronto. We have lately received a volume of 253 pages containing the papers read before the Society during the session 1894-95. The papers refer to both the theoretical and practical sides of engineering, and their publication cannot but encourage investigation among the students. A plan adopted by this Society, and by a number of American societies of a similar kind, is worth noting. Before a paper is read, 150 proofs of it are distributed among engineers and specialists interested in the subject with which it deals, and their opinions upon any particular point are invited. The replies received are read after the paper, and help to make the discussion more general and of greater value than it otherwise would be.

The Corporation of the Massachusetts Institute of Technology, Boston, have a good understanding of what technical education means. The following paragraph, from the *Calendar* of the Institute received a few days ago, should be borne in mind by the organisers of technical education in this country:—"The foundation of all sound technological education requires not only thorough theoretical training, but also prolonged, well-directed laboratory drill which shall first give the student the power of close and accurate observation, and then bring him into direct contact with the material problems of his future profession." It is by acting upon this educational principle that the Massachusetts Institute has gained such a large measure of success.

Tables showing the number and proportion of pupils attending secondary schools in London are given in the *Technical Education Gazette*. The returns obtained show that the number of pupils receiving education in 84 public endowed and public proprietary schools is 19,072, and the number receiving education ni 126 private or semi-private schools is 7107. The proportion which pupils attending secondary schools bear to those attending public elementary schools, may be gathered from the fact that the number per 100,000 of the population attending secondary schools is 623, while the number per 100,000 of the population attending public elementary schools is 16,904.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, vol. i. No. 8 (May 1895).—Kinetic stability of central orbits, by Prof. Woolsey Johnson, contains an investigation, of an elementary character, of a problem not discussed in the fourth edition (p. 125) of Tait and Steel's "Dynamics of a Particle." It is a satisfactory discussion of the problem so far as it relates to central orbits. The note was read before the Society at its April meeting.—Dr. J. Pierpont, in a short paper, read before the Yale Mathematical Club, entitled "Lagrange's place in the Theory of Substitution," though he cannot vindicate Lagrange's right to the title of creator of the theory of substitutions, presents a few examples of his methods in order to show the importance of considering him from this point of view. "Lagrange was led to the study of this theory by his attempts to solve equations of degree higher than the fourth."—Gauss's third proof of the fundamental theorem of algebra, by Prof. Bôcher, indicates the connection between Gauss's third proof that every algebraic equation has a root and those branches of mathematics which have since been developed under the names of the theory of functions and the theory of the potential. The notes, among other details, give the different courses of lectures in mathematics at American and European colleges.—There is the usual long list of new publications.

Wiedemann's Annalen der Physik und Chemie, No. 5.—Wave-lengths of ultra-violet aluminium lines, by C. Runge. The lines of the spark spectrum near 186 μ wave-length are of great intensity, and may be used as standards of reference. They were therefore carefully determined by means of a Rowland concave grating and sensitive plates prepared by Schumann's method. They were compared with the spectrum of iron, and referred to Rowland's standard wave-lengths for that substance. The figures for the four lines at 760 mm. pressure and 20° C. were 1854·09, 1862·20, 1935·29, and 1989·90. The wave-lengths reduced to a vacuum would be about 0·6 units greater.—On the dichroism of calcspar, quartz, and tourmaline for infra-red rays, by Ernest Merritt. The absorption of the infra-red rays in these substances depends upon the plane of polarisation. Especially in calcspar and in tourmaline the two curves representing the transmittency for the ordinary and the extraordinary ray, respectively, are quite different, so that they appear to be independent of each other. The following absorption bands were observed in these curves: Calcspar, at 2·44 μ and 2·74 μ for the ordinary ray. These are very sharp. Some broad bands also appear at 3·4 μ, 4 μ, and 4·6 μ. The extraordinary ray is absorbed at wave-lengths of 3·28, 3·75, and 4·66 μ. Quartz shows an absorption band for the ordinary ray at 2·9 μ. When the wave-length exceeds 4·75 μ the substance is practically opaque for both rays. Tourmaline absorbs the ordinary ray of wave-length 2·82 μ. The two curves intersect at 2·30 μ and again at 3·84 μ, so that between these two points the dichroism of tourmaline is reversed.—On the transmittency of solid bodies for the luminiferous ether, by L. Zehnder (see p. 153).—On the measurement of high temperatures with the thermo-element and the melting-points of some inorganic salts, by John McCrae. The melting-points of a number of salts, chiefly alkaline haloids, were determined by means of a platinum and platinum-rhodium couple, whose E.M.F. is proportional to the temperature between 300° and 1400°. The temperature of the alcohol flame, as shown by the same couple, was 1488°, and that of the Bunsen flame at its hottest part, 1725° C.—On electric resonance, by V. Bjerknes. This is an important contribution to the theory of Hertzian oscillations. The author considers the effect of the periods of the oscillator and the resonator, and their logarithmic decrements, together with a constant measuring the intensity of the oscillations. He thus arrives at several fundamental laws, such as: The secondary spark potential is proportional to the square of the period of the resonator, the magnetic or thermal integral effect to its cube, and the electric integral effect to its fifth power.

SOCIETIES AND ACADEMIES.

London.

Physical Society, June 14.—Captain W. de W. Abney, President, in the chair.—Mr. Burstall continued the reading of his paper on the measurement of a syclically varying temperature. Three sizes of platinum wire have been employed for the thermometers in order that some idea might be formed as to the magnitude of the error caused by the lag of the temperature of the wire behind that of the gases. The constants of the platinum thermometers were determined either by comparison with a standard Callendar platinum thermometer or by means of

[illegible], boiling water and boiling sulphur. In most cases the thermometer constants were determined after the wire had been exposed to the action of the hot gases for about half an hour. One wire, however was calibrated before being used, and an unusually high value was obtained for the coefficient δ. After this wire had been exposed to the hot gases, the value of δ fell, however, to the normal. The author thinks the abnormal value may have been due to the formation of a gold platinum alloy during the process of attaching the wire to the leads, and that this alloy was subsequently swept off by the hot gases. The paper includes a number of tables and curves which embody the numerical results, and show that concordant results can be obtained on different days and with different thermometers. Prof. Perry said that an instrument for quickly recording varying temperatures was greatly required by engineers. The temperature just inside the cylinder walls was, however, the most important to determine, and a knowledge of how the temperature from 1 to 2 m.m. inside the walls varied would be of the greatest importance. He would like to ask the author if the observed temperatures agreed with the values calculated on the assumption that the gases in the cylinder behaved as a perfect gas, and that $\frac{PV}{T}$ was constant during the whole stroke. Differences between the observed and calculated values might be due to dissociation, and not entirely to lag in the thermometers. It was astonishing that even the fine wires employed were able to follow the rapidly varying temperature, and he would like to see some special experiments made to test this point. Prof. Capper showed a diagram giving the values calculated on the assumption that $\frac{PV}{T}$ = constant. In such a calculation it was necessary to assume some temperature as a starting-point, and in general this temperature was obtained from an analysis of the exhaust gases, so that the calculated curve is most likely to depart from the truth at the commencement of the stroke. He, Prof. Capper, hoped that the author would be able to accurately determine the temperature of some one point of the stroke, and he suggested that the point where the observed curve crossed the theoretical curve would be the most suitable one for this purpose. Such a point must exist, since at the commencement of the stroke the lag causes the observed temperature to be too low, while at the end of the stroke the observed temperatures are too high. Mr. Burstall finds a curious bump in his curves, and it is curious that a similar bump exists in the calculated curves. From the constancy with which this bump appears, it would seem that it must have some physical meaning. It was important to remember that the expansion in the gas-engine cylinder is not adiabatic, for heat is both abstracted and generated during the stroke. Mr. Blakesley suggested that since the temperatures dealt with were sufficient to make the wire red-hot, the question arose whether lag might be investigated by the wire being examined by means of Becquerel's phosphoroscope, at a known interval after the removal of the source of heat. Mr. Griffiths said he considered an important source of error was the large thermal capacity of the leads when the working wire was so very short. He thought it would be possible to standardise the thermometers under conditions similar to those which occur in the engine cylinder. Thus perhaps alternate gushes of air at 0° and 100° C. might be used. The use of gold to attach the fine wire to the leads was objectionable, since the gold must permeate the platinum for quite an appreciable fraction of the whole length of the wire. He would like to know whether the change in δ alluded to by the author occurred with the first explosion, or whether it was a gradual one. Mr. Enright pointed out that the nature of the working substance in a gas engine varied during the stroke. Prof. Perry said that the change in the specific volume of the gases before and after combustion did not amount to more than 1·25 per cent. Mr. E. Wilson said he thought it was most important to shorten the time of contact, since at present the galvanometer readings corresponded to the mean temperature over a range of about 5 per cent. of the whole stroke. It might be possible to make use of a condenser to get over this difficulty. Prof. Rucker said that the Kew Observatory were making arrangements to undertake the testing of platinum thermometers. Mr. Enright suggested that with a very short contact induced currents might cause errors. Mr. [illegible] said that he had found that the method of determining the zero point of thermometers, by means of melting ice, was far from satisfactory, and that the results obtained could not be depended upon to within 0°·1 C. The author, in his reply, said the only chemical action on the wires he thought probable was the formation of a carbide. After several hours use, however, the wires appear quite bright and clean. Mr. N. E. Deerr read a paper on the thermal constants of the elements. The object of the paper is to establish the following laws: If T denote the melting-point on the absolute scale, C the mean coefficient of expansion between zero and the melting-point, S the mean specific heat, and L the latent heat of fusion, then, for any family in Mendeléef's periodic classification, the following relations will hold between metals and metals, and between non-metals and non-metals:

$$\left(T + \frac{L}{S}\right)C = \text{const.}$$

$$TC = \text{const.}$$

$$\frac{LC}{S} = \text{const.}$$

In the absence of other data, the mean values of C and S between 0 and 100° have been taken. Anomalous values are obtained in the case of gold and mercury, if these metals are included in their usual positions. The author considers that the thermal constants indicate that gold ought to be placed among the transition elements. He further proposes to place mercury in a new group to come before the lithium group. Such a group, he suggests, would contain hydrogen, argon and mercury. The paper concludes with an attempt to justify the expression

$$\left(T + \frac{L}{S}\right)C = \text{const.}$$

on theoretical grounds. Dr. Gladstone considered that the paper contained valuable numerical relationship, and that the second and third formulæ were much more strongly supported by the data given than the first formula. He, the speaker, had previously noticed that the elements of the transition group might be subdivided into sub-groups, and that the elements of each of these sub-groups were particularly closely related. He agreed with the author that gold ought not to be included in the first group. Mr. F. H. Neville said that since the author did not give the source of the data he had employed, most of the results given were rather indefinite. For example, while the author gives 870 as the melting-point of aluminium, Mr. Haycock and himself had found the value 927°. The value of the latent heat of aluminium given was 29·3, while Pionchon, in a recent paper in the *Comptes rendus*, gives the value 80. Theoretical considerations appear to indicate that 80 is the minimum value possible. The author assumes that when you heat a substance from the absolute zero to its melting point, all the energy supplied is expended in the work of expansion. Some of the heat, however, must be employed in changing the kinetic energy of the molecules, even in the case of a solid. Prof. Worthington said that in some cases the amount of work done against cohesive forces between 0 and 100° was much less than one ten-thousandth of the whole amount of energy supplied. Mr. Griffiths said he did not believe in any generalisation which depended on the values of the specific heats determined between 0 and 100°, the rate of change with temperature of specific heat being so great. The author in his reply said he had made every endeavour to obtain the most accurate data for his calculations. The value 29·3 for the latent heat of aluminium was obtained from a paper by J. G. Richards.—A paper on an electromagnetic effect, by Mr. F. W. Bowden, was postponed till the next meeting.

Entomological Society, June 5.—The Right Hon. Lord Walsingham, F.R.S., Vice-President, in the chair.—Dr. Sharp, F.R.S., exhibited, on behalf of Dr. G. D. Haviland, two species of *Calotermes* from Borneo, the individuals being alive and apparently in good health; one of the two small communities (which were contained in glass tubes) consisted of a few individuals of the immature sexual forms and of a neoteinic queen; this latter had increased somewhat in size during the eight months it had been in Dr. Haviland's possession, but no eggs had been deposited, neither had any of the immature individuals developed into winged forms. The second community exhibited consisted entirely of the immature sexual forms, and this community had produced numerous winged adults while it had been in Dr. Haviland's possession. Specimens were also exhibited to illustrate the neoteinic forms that were produced in Borneo after a community had been artificially orphaned. As regards these, Dr. Sharp expressed

the hope that Dr. Haviland would shortly publish the very valuable observations he had made. In the case of a species of fungus Termite, Dr. Haviland had found that the community had replaced a king and queen by normal, not by neoteinic forms.—Mr. McLachlan, F.R.S., exhibited examples of the female of *Pyrrhosoma minium*, Harris, having the abdomen incrusted with whitish mud through ovipositing in a ditch in which the water was nearly all dried up. He had noticed the same thing in other species of Agrionidæ.—Mr. Roland Trimen, F.R.S., exhibited some specimens of "Honey" Ants, discovered at Estcourt, in Natal, about a year ago, by Mr. J. M. Hutchinson. The species has not been identified, but is quite different from *Myrmecocystus* and *Camponotus*—the genera which have long been distinguished as containing species, some of whose workers are employed as living honey-pots for the benefit of the community. The specimens exhibited included six "globulars"—to use Mr. McCook's term in regard to the American species, *Myrmecocystus hortus-deorum*—all with the abdomen enormously distended with nectar; but other examples presented to the South African Museum by Mr. Hutchinson comprised various individuals exhibiting different gradations of distension, thus indicating that the condition of absolute repletion is arrived at gradually, and may possibly be reached by some few only of those individuals who feed, or are fed, up for the purpose. Certainly, in the nests examined by Mr. Hutchinson, in Natal, the number of "globulars" was very small in proportion to the population of ordinary workers; and it is somewhat difficult to understand of what particular value as a food reserve so very small a quantity of nectar so exceptionally stored can be. Mr. Trimen added that while the occurrence of "Honey" Ants in Southern, North America, South Australia, and he believed also in India, was well known, the Natal species now exhibited was the first African one that had come under his notice.—Dr. Sharp exhibited a series of Coleoptera, to illustrate variation in size.—Herr Brunner von Wattenwyl made a communication informing the Society that a most unfortunate error had crept into the table of genera in his Monograph of *Pseudophyllides*; on page 9, line 1, and on page 13, line 37, instead of "mesonotum" should be read "mesosternum."

Geological Society, June 5.—W. H. Hudleston, F.R.S., Vice-President, in the chair.—On a well-marked horizon of Radiolarian rocks in the Lower Culm Measures of Devon, Cornwall, and West Somerset, by Dr. G. J. Hinde and Howard Fox. In the Lower Culm Measures the basal *Posidonomya*-beds and the Waddon Barton beds with *Goniatites spiralis* consist of fine shales with thin limestones, and above these are the beds which form the subject of the present paper. The Upper Culm Measures consist of conglomerates, grits, sandstones, and shales, with occasional beds of culm. There is evidence of the partial denudation of the radiolarian rocks during the accumulation of the Upper Culm beds, as indicated by the presence of pebbles of the former in the latter. The radiolarian beds consist of a series of organic siliceous rocks—some of a very hard cherty character, others platy, and yet others of soft incoherent shales. The term "grits," which has been used in connection with these beds, is a misnomer; there are beds which are superficially like fine grits, but they are found to be radiolarian deposits. At present there are not sufficient data for estimating the thickness of the radiolarian deposits; but they are probably some hundreds of feet thick, though the whole does not consist of beds of organic origin. In a quarry in the Launceston district 50 feet of radiolarian cherty rock are seen without admixture of shale. A detailed description of the lithological characters of the rocks of the series was given, and analyses by Mr. J. Hort Player; a marked feature of their composition is the very general absence of carbonate of lime. The microscopic characters of the rocks were also described, and the small amount of detrital matter in the beds of the series was noted. The fossils tend to confirm the view that the Lower Culm Measures are the deep-water equivalents of the carboniferous limestone in other parts of the British Isles, and not shallow-water representatives of deeper beds occurring to the north, as was formerly supposed. In connection with this it was noted that the deep-sea character of the Lower Culm of Germany, which corresponds with our Lower Culm Measures, was maintained by Dr. Holzapfel even before the discovery of radiolaria in the beds of Kieselschiefer furnished such strong evidence in support of this view.—The geology of Mount Ruwenzori and some adjoining regions of Equatorial Africa, by G. F. Scott-Elliot and Dr. J. W. Gregory. Ruwenzori is a mountain between the Albert and Albert Edward Nyanzas. Topographically it is a narrow ridge which extends for about 50 miles in a direction from north-north-east to south-south-west. Its summit attains a height of 16,500 feet. The western slope is at an angle of 22°; the eastern slope at about one of 4°. The authors described sections across the ridge at right angles to its trend. These showed that Ruwenzori is not volcanic, nor is it a simple *massif* of diorite. Epidiorite occurs only as banded sheets in the schists on the flanks of the mountain, and is not the central rock of the ridge. The strike of the flanking schists seems to run concentrically round the ridge as though the central rock were intrusive into them. The highest rock collected, a coarse-grained granite or granitoid gneiss, may be an intrusive igneous rock, but it may be part of the old Archæan series faulted up; there is nothing in its microscopical characters to separate it from the Archæan rocks, and the authors thought it probable that this rock was raised into its present position by faulting. In this case Ruwenzori is simply composed of an orographic block or "scholl," which was at one time probably part of a wide plateau of Archæan rocks. There is abundant evidence of volcanic action around Ruwenzori, for the plains, especially to the east and south-east, are studded with small volcanic cones, arranged on lines which radiate from Ruwenzori. Evidence points to the former occupation of the Nyamwamba, Mubuku, and Batagu valleys by glaciers, *roches moutonnées* of typical character having been noted in the two former valleys. The country round Ruwenzori consists of rocks which may be conveniently grouped into two series—one composed of gneisses and schists, and the other of non-foliated sediments. The former (the Archæan series) are of the type that has an enormous extension in Equatorial Africa, and forms the main plateau on which all the sediments and volcanic rocks have been deposited. The sedimentary rocks are probably Palæozoic, possibly pre-carboniferous, but in the absence of fossils it would be unsafe to go beyond this statement.—On overthrusts of tertiary date in Dorset, by A. Strahan. The results given in this paper were obtained during a re-survey of South Dorset on the 6-inch scale. The disturbances can be divided into two groups—the one being mainly of Miocene date, and the other of intra-cretaceous (between Wealden and Gault) age. The former includes the Isle of Purbeck fold (which is the continuation of the Isle of Wight disturbance), the Ringstead fold, the Chaldon and Ridgeway disturbances, and the Litton Cheney fault. In the latter are placed the anticline of Osmington Mill, the syncline of Upton, and a part of the anticline of Chaldon; farther west the Broadway anticline and Upway syncline, a fault at Abbotsbury, and many other folds come into the same group. These earlier movements led to the well-known unconformity at the base of the Upper Cretaceous rocks.

Linnean Society, June 6.—Mr. W. Percy Sladen, Vice-President, in the chair.—The minutes of the last meeting having been read and confirmed, the Chairman, on behalf of the President, declared the following to be Vice-Presidents:—Messrs. J. G. Baker, F. Crisp, A. Lister, and W. P. Sladen. Mr. B. B. Woodward was elected a Fellow.—Mr. M. Buysman, who has laboured for many years to establish a garden at Middleburg for economic plants, exhibited specimens to show the excellence and completeness of his preparations.—On behalf of Mr. T. J. Mann, who had lately returned from Ceylon, Mr. Harting exhibited specimens of a butterfly, *Catophaga galena*, Felder, which had been observed migrating in thousands across the northern part of the island during March and April last, in a direction from north-east to south-west. The movement commenced about 7 a.m. and lasted until noon, when it decreased, and was resumed in the afternoon for another two hours. Mr. Harting referred to the remarks on this subject made by Sir J. Emerson Tennent ("Nat. Hist.," Ceylon, 1861, p. 404, note) to the observations of Darwin on the countless myriads of butterflies met with at sea some miles off the mouth of the Plata, and to a paper by Mr. R. McLachlan on the migratory habits of *Vanessa cardui* (*Entom. Mo. Mag.*, xvi. p. 49). He did not think that the movement was analogous to the migration of birds which migrated in opposite directions in spring and autumn, for the insects moved only in one direction, and did not return, vast numbers perishing *en route*. The phenomenon rather resembled what had been observed in the case of lemmings, locusts, and dragon-flies (Weissenborn, *Mag. Nat. Hist.*, n.s., vol. iii. p. 516), and might be explained as a sudden exodus from the birthplace, leading to a compensating reduction of the species after a season exceptionally favourable to its increase. His

remarks were criticised by Colonel Swinhoe, who was inclined to confirm this view, and by Mr. Kirby, who referred to the particular species which were found to take part in these so-called "migrations."—A new *Distomum* was described by Mr. G. West, whose observations were favourably criticised by Mr. W. P. Sladen and Prof. Howes.—On behalf of Mme. van der Bosse, Mr. George Murray communicated a description of a new genus of Algæ (*Pseudocodium*), the characters of which were minutely pointed out by means of specially-prepared lantern slides.—A paper was then read by Mr. A. Vaughan Jennings on the nature of *Mœbiusispongia parasitica*, on which critical remarks were made by Prof. Rupert Jones and Mr. F. Chapman.—A second paper by Mr. Vaughan Jennings contained a description of a new genus of Foraminifera of the family *Astrorhizidæ*.

PARIS.

Academy of Sciences, June 10.—M. Lœwy in the chair.—On the Meudon Physico-Astronomical Observatory, by M. J. Janssen. An account of the present state of the Observatory and of the difficulties through which it has passed on account of the reductions made in the State grants and appropriations, together with some details of the work done since 1876.—On the necessarily harmonic form of expression, for the displacements of each particle in an ocean roller, as a function of the time, by M. J. Boussinesq.—Note on the photographic surveys executed in 1894 by the Canadian engineers and the United States Coast and Geodetic Survey Service for the delimitation of Alaska and British Columbia, by M. A. Laussedat. This is an account of the spread of the Canadian method into the United States Service, and a review of the general adoption of similar processes in other countries.—Solar observations made at Lyons Observatory during the first quarter of 1895, by M. J. Guillaume.—On algebraical curves of constant twist and on algebraical minima surfaces inscribed in a sphere, by M. E. Cosserat.—New theorems in arithmetic, by P. Pepin.—On an explosive system capable of demonstrating the rotation of the terrestrial globe, by M. Jules Andrade.—Spectroscopic study of carbons from the electric furnace, by M. H. Deslandres. Two carbon poles used in M. Moissan's electric furnace were examined. Those parts of the carbon removed from the arc showed the usual spectra of impurities, whereas the parts in the arc were free from all impurities except calcium. The growths on the negative pole were of greatest purity, and furnished carbon spectra showing wave-lengths (cited) much fewer than those recorded for carbon by Hartley and others. The purification of the carbons by the passage of the current in the arc is due to the volatilisation of the more volatile constituents at the high temperature obtained.—On sensitive flames, by M. E. Bouty.—Physical properties of acetylene; acetylene hydrate, by M. P. Villard. A table of pressures corresponding to certain temperatures is given for acetylene, together with a table of dissociation pressures for the hydrate of acetylene. This hydrate resembles the hydrates of nitrous oxide and carbon dioxide, and is represented as $C_2H_2.6H_2O$. Its heat of combination is 15·4 Cal. per molecule, very near to the value, 15·0 Cal., obtained for carbon dioxide and nitrous oxide.—Synthetical production of nitro-alcohols, by M. Louis Henry.—Condensation of aldehydes and saturated ketones, by MM. Ph. Barbier and L. Bouveault. The researches detailed appear to establish the fact that only ordinary acetone can condense easily with aldehydes; on the other hand, as the molecular weight of the aldehydes increases, the aptitude for condensation with acetone diminishes, and the principal reaction becomes the condensation of the aldehyde itself.—On the causes of the colouration and the coagulation of milk by heat, by MM. P. Cazeneuve and Haddon. The conclusions are drawn: (1) That the yellowing of milk by heat is due to oxidation of lactose in the presence of the alkaline salts of the milk; (2) the oxidation of lactose produces acids, formic among others, and hence causes coagulation of the milk; (3) the coagulated casein is not itself altered, but is merely tinted by the decomposition products of lactose.—Esters of the active α-oxybutyric acids, by MM. Ph. A. Guye and Ch. Jordan.—On the history of the alkaloids of the Fumariaceæ and Papaveraceæ, by M. Battandier.—Contribution to the study of germination, by M. Th. Schlœsing. The germination of lupin seeds or wheat does not entail an appreciable loss of nitrogen in the gaseous state.—On amylase, by M. Effront.—The Cecidomyia of oats (*Cecidomyia avenæ*, nov. sp.), by M. Paul Marchal.—The epidermal cell of insects: its paraplasm and its nucleus, by M. Joannes Chatin.—On the relation of the thermal springs of Néris and Evaux with ancient faults of the Central Plateau, by M. L. de Launay.—On the succession of fauna of the Upper Lias and Lower Bajocien in Poitou, by M. Jules Welsch.—Researches on the modifications of nutrition in persons suffering from cancer, by MM. Simon Duplay and Savoire. The differences observed in amounts of urea and phosphoric acid excreted by cancerous patients, as compared with the normal healthy excretion, are due entirely to defective nutrition, and disappear when a suitable régime is used. These differences cannot be used for purposes of diagnosis.—On the use of chloride of lime and its mode of action against the bite of venomous serpents, by MM. C. Phisalix and G. Bertrand.—Storms of five days from May 20 to May 25, 1895, in Bohemia, by M. Ch. V. Zenger.

THURSDAY, JUNE 27, 1895.

"THE WIZARD OF MENLO PARK."

The Life and Inventions of Thomas Alva Edison. By W. K. L. Dickson and Antonia Dickson. (London: Chatto and Windus, 1894.

THE present rapid increase in the number of places where the Edison Kinetoscope is exhibited, leads one to glance through the account which was published towards the end of last year of the life and adventures of the American inventor. The career of one who started as a newsboy, and who has raised himself to fame and wealth by his quickness of perception, fertility of resource, and general shrewdness, has been too varied and exciting for the authors to succeed in rendering the narrative uninteresting.

But the pages of rhapsody with which this long quarto book is filled, combined with the extremely verbose and grandiloquent style in which it has been written, not only render the meaning well-nigh unintelligible in many places, but give a wholly false notion of Mr. Edison's character. For those who have met him must have been struck with his somewhat boyish character, his fondness for a joke, and his objection to black coats, tall hats, and formality. The Edison of this book would hardly be recognised as the Edison who, we remember, some years ago could not be induced to put on his coat or shoes to receive an English peer, well known to science, who happened to call at Menlo Park when the inventor was taking his afternoon nap.

We start, of course, with Edison's pedigree, and we are told that his father, "Samuel Edison, however, was not minded to stimulate the waning flames of patriotism by a libation of personal gore." We should have thought the father of an inventor would have known that gore was not a good sort of kindling. Then comes a description of "callow collegians dragged through an uncongenial course of study, boarding-school graduates steeped in a weak solution of accomplishments, ephemeral creatures on whose glossy plumage the dews of Parnassus have no power to rest"; but Edison, on the contrary, "despite his paucity of years," read through "fifteen feet of closely serried volumes." Then we come to an excellent portrait of Edison at fourteen years of age, which strikingly resembles the closely shaven Edison of to-day, and shows the same merry twinkle of the eye.

Facsimiles are given of pages of Edison's newspaper, the *Grand Trunk Herald*, started in 1862, the vast number of blots on which are explained, we suppose, by the fact that this newspaper was regularly composed and printed in a dilapidated freight car attached to a running train. His next venture in the newspaper line, *Paul Pry*, led to his being ducked by a subscriber, and, as his travelling railway printing establishment and laboratory were burnt, through the constant jolting of the springless car shaking the cork out of a bottle of phosphorus, he turned his attention to the construction of a telegraph line. This was not attended with success, since to produce an electric current, "Edison secured two Brobdingnagian cats, with volcanic tempers, attached a wire to their legs, administered a violent amount of friction to their backs, and breathlessly awaited developments."

Afterwards he became a real telegraph operator, and when on night duty in the service of the Grand Trunk Railway of Canada, he was, in common with the other night operators, required to signal the word *six* every half-hour to show that he was awake. Preferring, however, to wander about the town, he obtained a clock and converted it into an automatic telegraph key. This key, however, would do nothing more than periodically signal the word *six*, and declined to answer inquiries, so a detective operator was put on the track, and Edison had to make his escape into the United States.

During the severe winter which followed, the ice broke the telegraph cable under the river which separates Port Huron from the Canadian city of Sarnia, on the opposite bank a mile and a half away, and further rendered all traffic across the river impossible. Communication between the two cities was, however, restored by Edison using the alarm whistle of a locomotive engine to send Morse signals. This power of overcoming difficulties brought him into public notice, and he obtained in succession several good posts as a telegraph operator. His love of fun and of making experiments, however, led him into constant trouble; but he was rewarded at the age of seventeen by making his first invention of an instrument for automatically repeating a telegraphic message.

Edison's electric device for killing cockroaches "is told in the prosaic terms of the nineteenth century," and commences, "Curiosity betrayed our Mother Eve," and so on for many lines. Edison's first patent for a "Vote Recorder" was not commercially successful, as its employment in the Massachusetts Legislature was found to interfere with the power of the House to use "*filibustering.*" Then come his Universal Stock Printer and his employment as operator by the Law's Gold Reporting Company.

During the excitement connected with the operations of the Gould and Fisk ring to make a corner in gold, the stock quotation printer broke down, and Edison gave the very simple explanation that a contact spring had broken and fallen between two cog-wheels in the instrument. To describe this, however, the authors require several pages. "Inflamed by the lust of gold" (not Edison, however, for he was very poor at the time and owed 200 dollars), "and reduced to the semblance of insatiate brutes, the great sea of sentient humanity surged around the shrine of its desires," &c.

Chapter iv. commences with a description of "Edison's storm-tossed craft," and tells how "a steady gale blew from the Blessed Isles, wafting the adventurer into all tempting harbours of successful discovery." We much doubt the value of a wind blowing *from* an island, whether blest or not, to take a craft into its harbour.

In 1870 he was developing his automatic telegraph for transmitting a message by the use of a perforated strip of paper, and receiving it in Roman characters at the other end of the telegraph line; also instruments for automatically sending messages, using the Morse code, as in the well-known Wheatstone's Fast Speed instruments.

Next came the carbon button and the loud-speaking telephone. No reference is here made to Prof. Hughes' microphone, or to the controversy which was carried on

about 1876, as to who invented the carbon telephone transmitter, and we are told that the Edison carbon transmitter "held the monopoly of the telephone in England for many years." In the next chapter, "the pretensions of his rival" are touched on, and Edison's remark, that "one of the biggest steals ever made was filched directly from my telephone," is quoted.

"The individual mistress of Edison's heart until now had been science, but a new potency was at hand equally strong, but immeasurably more subtle and all-pervading." Then the authors drop into poetry, which they have a way of doing on all possible occasions. Later on we are told that "prior to his marriage Edison portioned out the hours of sleeping and waking by the ebb and flow of the Divine afflatus," and that his "blood after having served the purpose of stimulating the capillary vessels of the brain, and inducing inventive capacity, soon retreats quietly to its legitimate source." We note in this chapter references to "Mrs. Noah's superior faculties," the Roman Empire, Carthage and her glory, a Phœnician axiom, and a disquisition on "the sickly and mercurial sentimentality of the Oriental and Latinic races," "the Plutonian broths of Sparta," "the delicious pastoral flavour to the *Allegretto* and the *Lycidas*." We presume Milton's title "l'Allegro" was not long enough for the authors; and all this while Edison has been left gazing at a test-tube in a large photograph on page 95 of this book.

By 1876 forty-five of his distinct inventions were in different processes of completion; £100,000 had been realised from the manufacture and the sale of patents; and the throng of sight-seers to Edison's laboratory at Newark became so great that he moved to Menlo Park, twenty-four miles from New York, and stacked there his "cases of every ordinary and extraordinary device born of that prolific parent, necessity."

The first sketch of the phonograph, on p. 123, is of real interest, for we regard the phonograph as scientifically the greatest of Edison's achievements, in that Edison accomplished with its use, in an extremely simple way, what the previous elaborate talking-machines could not perform. But why the microscopic examination of the tin-foil showed that "the feminine members of the alphabet were less aggressive in their outlines than their masculine coadjutors," or why the "long E vindicated her rights to female enfranchisement," we know not.

Descriptions of various forms of phonographs, phonographic dolls, &c., take us to the end of chapter xi. Chapter xii. is devoted to telegraphing from trains in motion, a subject that is certainly worthy of more consideration than it has yet received, and to Edison's pyromagnetic motor, which, from its principle of construction, could never have been commercially successful.

The chapters on the development of the glow-lamp by Edison, and those associated with him, are some of the most interesting in this book. Phlegmatic indeed must be the reader who does not feel inspired by the enthusiasm which led Edison to despatch Mr. Moore to search through China and Japan, Mr. McGowan to explore the American continent from the Atlantic to the Pacific, and Mr. Ricalton to seek in India, Ceylon, and the neighbouring countries for a vegetable fibre suitable for being carbonised into a glow-lamp filament. But, if the reader be of a critical temperament, his pleasure at reading the account of these explorations will be diminished by the many faults which mar the description.

For example, the large picture on p. 217 of "Cingalese Women, photographed by Mr. Ricalton in his Search for Fibre," was never taken in Ceylon, since it is obviously a photograph of a group of *Japanese* girls posed in front of a theatrical back scene. One of these girls is sitting on a Western rustic garden-chair; so, perhaps, the photograph was taken in New York or Paris, on the principle followed by the special correspondent in the Soudan war, whose envelopes bore the St. John's Wood post-mark. Oddly enough, the book contains several other photographs of Cingalese people taken by Mr. Ricalton; but the authors do not seem to have been struck with the fact that a comparatively small island like Ceylon should have possessed inhabitants of such a variety of different types.

A great deal of tall talk follows about Edison's work on the dynamo machine. "Ah! potent wizard, you shame the records of the Arabian nights and the fabled glories of the East," &c., with the following surprising bit of information for the Englishman: "To-day there is not a hamlet in England, however insignificant, which is not in vital connection with the central sources of supply," that is, has electric energy supplied to it from a central electric light station. Passing over pages of grandiloquence, we come to a long description of Edison's factory and laboratories at Orange. The pictures remind us of what we ourselves saw when visiting Edison, but we have no recollection that in the laboratory "fragrant gums and spices recall memories of the fair Babe of Bethlehem." In fact, what we chiefly remember was our surprise at the large number of phonographs which we saw in course of manufacture, and Edison's sallies of laughter at the simplicity of the English in being so easily gulled by limited liability companies.

Although this book is in parts as silly as anything we have ever read, it is nevertheless full of interest; for it gives a graphic picture of the struggles and success of one who is certainly remarkable for his quickness of insight, originality, and capacity for long stretches of hard work, even if we do not agree with the authors that he is "the greatest genius of this or any other age." Even if we were not told on the title-page that the book was written by W. K. L. and Antonia Dickson, we should feel quite sure that it was a joint production, one of the authors being Edison's superintendent of the experimental department in New York, and the other a poetic rhapsodist who has never read her "Mark Twain." The illustrations are well executed, the printing and paper good, and the general get-up of the book all that can be desired of an expensive quarto volume to lie on the drawing-room table. But why was it not edited? asks the English reader. "P. D."

CRIMINAL IDENTIFICATION.

Finger-print Directories. By Francis Galton, F.R.S. (London: Macmillan and Co., 1895.)

IT will be remembered that the Departmental Committee which reported in the beginning of last year upon the best method of identifying habitual criminals, re-

commended the adoption of the Bertillon system of measurement conjointly with the plan of taking finger-prints now associated in this country with the name of Mr. Francis Galton. He loyally disclaims the honour of being the first to use it; that rests with Sir William Herschel, of the Indian Civil Service. But it is really from the unwearied labours of Mr. Galton that the scientific certainty of the system has been fully proved. He has so simplified the processes of taking and recording the impressions of the finger, has invented so complete and intelligible a series of indications and formulas, that the system can now be worked with the greatest facility and with mathematical precision. Of the supreme value of the finger-print as a means of identification, there can be no manner of doubt. It is, as Mr. Galton happily describes it, "an automatic sign-manual subject to no fault of observation or clerical error, and trustworthy throughout life." The Committee above quoted fully recognised this. "Finger-prints," they reported, "are an absolute impression taken direct from the body itself; if a print be taken at all, it must be necessarily correct." But they were met with the difficulty of classification as applied to any large collection of impressions. Where these were comparatively few, the index adopted by Mr. Galton was admirable and most effective. But where the numbers rose to many thousands, as would of course be the case in a criminal register, it might be a serious question whether searches could be made with reasonable facility and dispatch. It was for this reason that the double system of identification was recommended, for the strongest point in the Bertillon plan of measurement as practised in Paris was its perfect classification. There the particular card required, giving the name and antecedents of an individual, "could be found as certainly and almost as quickly as an accurately spelt word could be found in the dictionary."

Since then Mr. Francis Galton has devoted much time and very highly skilled intelligence to enlarging his methods of indexing and proving beyond all question the usefulness of the finger-prints. He now tells us, in his new work on "Finger-print Directories," how these indexes may be most easily and surely constructed, how the work of reference and search can be easily and quickly performed. Of course the result is largely dependent upon the size of the directory, the number of "sets" of impressions that have been collected to compose it. Mr. Galton's experiments were made with two collections, one of 300 complete sets of finger-prints, the other with 2632. In both, even with the largest, he was entirely successful. "The efficiency of a directory," as he says, "depends on its power of breaking up, with the maximum of surety and the minimum of labour, a collection of sets into groups of which even the largest shall be easily manageable, so that when a group is designated as that in which the set searched for must be, if it exists anywhere in the collection, it shall be quickly discovered." The collection that Mr. Galton finds most easily manageable is not necessarily the smallest, but that which lends itself best to search, in its character and its form. The one he has adopted is the card catalogue: "a collection of separate cards stacked behind one another in the separate order of their formula." Mr. Galton timed himself in his examination of 156 sets in his largest collection, which fell all under the same formula. Eight searches were made, during which a total of 373 cards were examined, and the time taken was a little over thirty-six minutes. Mr. Galton could therefore get through ten cards per minute, the trouble of opening the drawer or other receptacle having been done by an assistant. It is interesting to note that Mr. Galton in his inquiries first accepted the "whorl" as the basis of classification, thinking that from its almost endless variety of shape it would be the most useful of the three forms of impression; but as he went on he discarded it in favour of the "loop," the plainer forms of which could be "classed numerically by the simple expedient of recording the number of ridges in each of them that are crossed by an imaginary line drawn between two definite termini."

For a minute and detailed account of the primary and secondary classification of finger-prints, as well as for the best methods of taking them and studying their forms, we must refer the reader to Mr. Galton's new book. This most useful work contains a number of woodcuts and ample indications for the instruction and guidance of the student, with a specimen-book directory for three hundred sets. But whether the index is in the form of a book or of cards, Mr. Galton affirms, on perfectly good grounds, that it is quite possible to have "a finger-print directory, even of three thousand sets or more, that shall discriminate to within two or three sets." There can be no question, therefore, but that the whole system has passed out of the academic stage into one of real practical usefulness; and we may expect to see it applied for other purposes than that of criminal identification. Now that it has been made really manageable, it may be strongly recommended, for instance, to the military authorities as an infallible method of checking desertion and fraudulent re-enlistment. It appears that out of 35,000 men who enlist annually, 5000 desert, and only half are recaptured. Of the other half many, undoubtedly, re-enlist. Although the exact number cannot be positively fixed, it is estimated at 600, all of whom defraud the exchequer to the value of their second bounty and outfit. If, however, the finger-prints of all recruits were taken on attestation, and a register formed on the plan of the directories constructed by Mr. Galton, indisputable evidence would be afforded which would certainly convict the re-enlisted deserter of his original offence

BIRDS, BEASTS AND FISHES OF THE NORFOLK BROADLAND.

Birds, Beasts and Fishes of the Norfolk Broadland. By P. H. Emerson. 8vo, pp. 396, illustrated. (London: David Nutt, 1895.)

AFTER reading the severe criticisms passed on the works of several eminent British ornithologists—especially as regards illustrations—in the introductory chapter to the volume before us, we hoped we were going to be rewarded by finding something that would eclipse all previous efforts, both in the way of letter-press and plates. But we do not hesitate to say that in both respects we are disappointed. After all the writing about the "caricatures" of Bewick, and the "monstrous and gaudy decorations" of Selby, Gould, and Dresser, we find

only a series of very ordinary photographs, many of which have evidently been done from mounted specimens, and, what is more, from badly mounted ones. As to the text, we fail to see the reason for interlarding it with a provokingly numerous series of provincialisms, which, although no doubt familiar enough to the dwellers in East Norfolk, are certainly not household words in other parts of Her Majesty's dominions. To Norfolk people the names of "Herring-Spink," "Reed-Pheasant," "Spinex," and "Draw-Water," doubtless have a meaning, but we should be somewhat surprised if all our readers are aware that they respectively indicate the gold-crest, bearded tit, chaffinch, and goldfinch. It is true that in most cases the author does introduce a better-known name in the course of his notices, but this is not so with the "reed-pheasant." In omitting all scientific names, we are by no means sure that Mr. Emerson is not right, seeing that these are constantly being changed, while *English* names are permanent; but then let us have *English* names, and not *Norfolk* ones.

In the introductory chapter the author says indirectly that not much has been left out in regard to the habits of British birds; and we cannot help adding that if any important omissions do occur, he has done but little in the way of supplying them. Writing of the wren, he observes that "the tomtit, as the Broadsmen call this pert, child-like little bird, always brings an affectionate smile to your face as you see his hopping, plump little body flitting over the bank, or running along the branches of a leafless tree, stopping every now and then to sing his loud-voiced song; for, though his is a little body, he has a mighty and pleasant song." This example cited is only one of many taken almost at random. The professed ornithologist surely does not want such descriptions, and if the book is intended for the eyes of ladies and young people, why are we treated on p. 211 *et seq.* to a very unnecessary anecdote concerning the amours of swans?

We will take it for granted that among the birds our author has correctly determined the species he notices, and has recorded all those found in the Broads; but in the case of the mammals he is far from exact. He states, for instance, that there are two kinds of bats found there, one of which is designated the common, and the other the large bat. By the former is doubtless meant the pipistrelle, but as to the species indicated by the latter title we have no clue; and surely there ought to be more than two species of bats in Norfolk. Among the voles, again, we have two species, respectively termed the "red mouse" and the "marsh mouse"; and, although the former may be the bank vole, we can scarcely recognise the common field vole under the latter inappropriate title, if so be that it is intended for that species. The Broadland rats which the author places a long distance after the mice and voles are likewise left in a state of hopeless confusion, and we quite fail to recognise what are the three kinds alluded to under the names of "big rat with [illegible] chest," "large brown rat," and "little red rat." If the author thinks he has got hold of new species, or even fashionable sub-species, why did he not submit his specimens to a specialist? But as it is, his notes are [illegible] to the scientific zoologist, and, we should think, of no great interest to the ordinary observer of nature.

In the chapter on frogs and toads, the author excels himself. Of these animals he recognises the following: viz. the "garden-toad," "water-toad," "running toad," "common frog," and "land-frog." To know what creatures are meant might perhaps tax the acumen even of Mr. Boulenger; but the notes on their habits are too naïve. The garden-toad, we are informed, "makes a form in the grass during the hot weather in which to shelter himself; and should you come upon him, he will squat with his bright eyes fixed upon you all the time." This merely records a fact known to every one; but what shall we say of the following concerning the running toad? "The chief thing in connection with this creature is the rockstaff that a man can quiet the most restive horse with the bone of a running toad, which, it is said, will swim against the stream. Yacht designers and others might well look into the matter." Apart from the grammar, what a rockstaff is, we do not know, and we are equally ignorant whether it is the toad or its bone that can swim against stream. A lack of information as regards species and habits is also displayed when the author comes to eels; and he seems to be totally unaware that some years ago the late Surgeon Day communicated an important paper on the breeding of these fishes to the *Proceedings* of the Cotteswold Naturalists' Field Club.

As to the literary style of the book, perhaps the less said the better; and although it may attain a popularity among the numerous frequenters of the Norfolk Broads, it is to be feared that it cannot take a high rank among zoological works.

R. Lydekker.

OUR BOOK SHELF.

Object-Lessons in Botany. Book ii., for Standards iii., iv. and v. Being a Teacher's Aid to a Systematic Course of One Hundred Lessons for Boys and Girls. By Edward Snelgrove, B.A. London: Jarrold and Sons.

It is not perhaps very often that elementary scientific books of the type to which the volume before us belongs, either meets with, or indeed deserves, much success. It is with the greater pleasure, then, that we feel that the author is to be congratulated on having succeeded in producing a really good series of lessons which will be most useful, either in guiding teachers in arranging their class work, or in enabling a student to acquire a knowledge of plants for himself. The series of lessons is progressively arranged, beginning with the simpler forms of leaves and stems, and passing on to the various types of flowers and fruits. The really excellent feature of the work is the method by which the student is led to examine actual plants. The book would probably be of little service to any one merely desirous of "getting up" the subject without troubling to form any practical acquaintance with the objects dealt with. The examples selected as types are well chosen, and the student or teacher receives plenty of hints as to other forms which he may usefully compare with them. Almost the only fault we have to find with the book is, after all, only a literary one; still, it seems a pity that the generic names of the plants should have been commenced with a *small* letter, especially in the chapters on botanical names. This, however, is a defect that can easily be remedied in a future edition, which soon should be needed, for we can cordially recommend the volume, both to the elementary teacher and student, as a thoroughly good one.

Dental Microscopy. By A. Hopewell Smith, L.R.C.P., L.D.S., &c. Pp. 119. (London: The Dental Manufacturing Company, Limited.)

STUDENTS of dental microscopy will find this work a valuable guide to the preparation, observation, and photography of microscopical sections of hard and soft dental tissues. The volume is practical throughout, and is illustrated by eight lithographed plates, from which typical structures may be readily recognised. It should prove of great assistance to workers in dental histology.

Organic Chemistry, Theoretical and Practical. By Prof. J. S. Scarf, F.I.C., F.C.S. Pp. 240. (London and Glasgow: W. Collins, Sons, and Co., Limited.)

WE find no feature which distinguishes this text-book from others "adapted to the requirements of the Science and Art Department, and of the London University." The book may assist students to pass the examinations for which it has been constructed, but it is not a desirable introduction to the science of organic chemistry.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Antiquity of the Medical Profession.

DR. BLACK displays a surprising facility of misapprehension greater than I should have supposed possible.

The final sentence of his letter runs thus:—"It would seem, then, from history, that the medical profession is quite as old as either that of theology or law."

Now since the first sentence of my essay contains the clause—"In rude tribes it is difficult to distinguish between the priest and the medicine-man"; and since various illustrations are then given of the union of the priestly and medical functions in the same individual; and since it is thereafter shown that this union long continues among early civilised peoples Egyptians, Babylonians, Hebrews, Hindus, Greeks it is a necessary implication that, as Dr. Black says, "the medical profession is quite as old as either that of theology or law." For if two professions are at first exercised by the same persons they are necessarily of equal antiquity. So that, strangely enough, Dr. Black points out to me a truth which it is one of the purposes of my essay to teach. I can only suppose either that he did not read the first part of the essay at all, or that before he had reached the end he had forgotten the beginning.

Westerham, Kent. HERBERT SPENCER.

Halley's Equal Variation Chart.

I HAVE read Mr. Ward's interesting letter on this topic in NATURE of May 30, p. 106. I embrace this opportunity to correct some typographical errors in my letter in the issue of May 23.

No. 974 (4) should be 977 (4).

In foot-note 3, p. 79, the title of atlas referred to should be 'Tabulæ Nautic*al* Variationes Magneticas Denot*antes*."

I have compared Mr. Ward's description of his own chart with my notes. He evidently is the lucky possessor of the exceedingly rare Halley chart 977 (4). I should be pleased to have him inform me if the word "Britanniæ" in the dedication is not spelt with two *t's*.

The size of the British Museum copy is about 48 × 57 cm., the shorter dimension being in an east-west direction: it is in a splendid condition.

The earliest mention made of Halley's Equal Variation Chart is found in "Histoire de l'Acad. de Paris," 1701, p. 9. The chart referred to there must be the above 977 (4), of which we now know that two copies exist the British Museum's and Mr. Ward's. L. A. BAUER.

The University of Chicago.

The Invention of the Net.

IN your number of February 28 (p. 417), Mr. R. I. Pocock suggests that the observation of a spider's web may have given rise to the art of netting. It is of interest to note that the following citation is found in a Chinese cyclopædia: "Yuen-kien Lui-han" (1701, tom. ccccxlix. *art.* "Chi-chu," 2):—"In 'Pau-puh-tsze' it is said, 'Tai-hau [or Pâo-hsî] made a spider his master and knitted nets.'"

In the "Yih-King," the oldest authority that ascribes to Pâohsî the invention of the net, no mention is made in this connection of spider (see Legge's translation, in the "Sacred Books of the East," vol. xvi. p. 383); but the above-quoted passage of "Pau-puh-tsze" is tantamount to prove such a view, as suggested by Mr. Pocock, to have already occurred among the Chinese in the fourth century, A.D., when the book was written by a Taôist recluse named Koh Hung.

June 17. KUMAGUSU MINAKATA.

The Bird of Paradise.

I DESIRE to call the attention of your readers to a fashion which in the month of May was at its height in London, and is now much patronised throughout the country. I refer to the wearing in hats and bonnets of a graceful spray of soft fine plumes with drooping or curly tips. These the milliners call Bird of Paradise feathers, the assurance being constantly given that they are *real.* They are often mixed with osprey tips, which, to the shame of womanhood, have so long been in fashion, and are still largely used. I may state on trustworthy authority that during the past season one warehouse alone has disposed of no less than *sixty thousand dozens* of these mixed sprays!

The Bird of Paradise most used in millinery is that obtained in the Papuan Islands and New Guinea. Mr. Wallace, in describing the *Paradisea apoda*, says: "From each side of the body, beneath the wings, springs a dense tuft of long and delicate plumes, sometimes two feet in length, of the most intense golden-orange colour and very glossy, but changing towards the tips into a pale brown. This tuft of plumes can be elevated and spread out at pleasure, so as almost to conceal the body of the bird." In his "Oiseaux dans la Mode" of October 20, 1894, M. Jules Forest bitterly deplores the destruction which has been going on during the last decade. He emphasises the fact that it is no longer possible to procure such perfect specimens as were common ten years ago, since the unfortunate birds are so hunted that none of them are allowed to live long enough to reach full maturity, the full plumage of the male bird requiring several years for its development! He further states that "the birds which now flood the Paris market are for the most part young ones, still clothed in their first plumage, which lacks the brilliancy displayed in the older bird, and are consequently of small commercial value." Since January 1, 1892, strict regulations for the preservation of the Bird of Paradise have been in force in German New Guinea, and M. Forest appeals to the English and Dutch Governments to follow their good example.

The common sense of every thoughtful woman must at once tell her that no comparatively rare tropical species, such as the Bird of Paradise, can long withstand this drain upon it, and that this ruthless destruction, merely to pander to the caprice of a passing fashion, will soon place one of the most beautiful denizens of our earth in the same category as the Great Auk and the Dodo.

The women of England are earnestly entreated not to countenance the sacrifice of this bird by encouraging the demand for its precious feathers. Let them resolve to do what they can to prevent the extermination of this "wonder of nature" by stoutly refusing to purchase or wear anything purporting to have once belonged to a Bird of Paradise.

MARGARETTA L. LEMON.

Redhill, Surrey, June 21.

THE TICK PEST IN THE TROPICS.

THOSE living in temperate climates have probably small idea of the virulence of insect and other pests in the tropics. A plague of caterpillars may destroy a season's crop in England, but there is the winter's frost to be passed through before a second attack need be feared. It is otherwise in the tropics. Vegetation is much more luxuriant, and the food supply is permanent; and, when once a plague has obtained a firm foothold

there is no apparent reason why it should cease its ravages before it has entirely destroyed its particular host. It is fortunate for agriculturists that the great increase of any particular parasite seems ultimately to work out its own destruction; and frequently when all hope seems over, the plague rapidly and unaccountably disappears.

Surprise has been expressed that ticks infesting cattle have received so little real study. Quite recently the statement appeared that these parasites formed the least known part of the tropical fauna. But a great deal has been done in this direction of recent years, and there seems some hope of real progress being made.

Taking the conditions into consideration, it is a matter of great wonder that so few ticks exist in many parts of the tropics. No real attempt has been made to decrease their numbers, and there appears to be no season of the year when the climate is fatal to them. Vegetation is rank, and we know now that they can live to a great extent upon vegetable matter; further, even where there is a scarcity of small indigenous mammals, there are plenty of horses and cattle. The multiplying powers of ticks are enormous. In one case I determined the number of eggs from one female as over 20,000 (see Fig. 3), and almost all of these were fertile and produced young ticks. The increase in numbers of ticks in most countries is not marked, however, and we are driven to the conclusion that there is here, in the animal kingdom, a waste of material analogous to that in the seeding of parasites and saprophytes among plants.

It is not surprising now and then to hear of a long-continued plague of ticks from one place or another where cattle-rearing is a staple industry. In Jamaica, it is by no means uncommon for the traveller to get covered with "grass-lice." On pushing aside the branches overhanging the riding path, I have been immediately covered with firmly attached young ticks which needed much care and patience to remove. The ticks of Jamaica are now a very serious source of anxiety in cattle-pens, and much loss is attributed to these parasites.

During my stay in Antigua, complaints were loud and frequent of the ravages of a large tick, which infested the cattle between the months of May and September. In the cattle and sheep farms of the Cape of Good Hope and Australia the "tick" matter is absorbing much attention. Specially large and annoying forms are described from parts of India, Central Africa and Central America; while extraordinary tales are told of the destruction caused by these parasites in cattle-rearing districts of South America. Elaborate and expensive researches have been conducted in the United States Southern Experimental Stations upon the life-history of the ticks and their relations to cattle; and the exhaustive reports, issued from the Bureau of Animal Industry, form by far the most valuable part of our economic literature on these pests.

The books of travellers teem with references to the annoyance caused by ticks. Sir Joseph Hooker, in his "Himalayan Journals," describes their abundance in the frontier regions between Sikkim and Nepaul, in pathless tracts destitute of animal life. He writes the following concerning the neighbourhood of Tonglo: "A large tick infests the small bamboo, and a more hateful insect I never encountered. The traveller cannot avoid these insects coming on his person (sometimes in great numbers) as he brushes through the forest; they get inside his dress, and insert the proboscis deeply without pain. Buried head and shoulders, and retained by a barbed lancet, the tick is only to be extracted by force which is very painful. I have devised many tortures, mechanical and chemical, to induce these disgusting intruders to withdraw their proboscis, but in vain."

Bates, on passing through the grassy lanes of the second-growth woods on the Amazons, often found himself covered by ticks. It occupied him, he says, a full hour after his day's work to clear himself of the parasites.

Belt refers to the "grass-lice" on the plains of Nicaragua, as quickly covering any one travelling through the country; so much so, that the herdsmen or "vacqueros" keep a ball of soft wax with which to rub themselves. The smaller ticks are thus removed from their skin, while the larger ones are picked off by hand.

Many a time, in walking through grass in the Leeward Islands, I have been conscious of the peculiar itching at the ankles caused by the attacks of "bête rouge." The bête rouge is not in reality a tick, although often confused with it. Horses seem to be particularly liable to its attacks, with the result that they lose all the hair about the face and eyes. In all probability the poor animals suffer a good deal, for the personal irritation is extreme. The bête rouge is exceedingly minute, and, as its name implies, is of a brilliant scarlet. At night, after retiring to rest, the warmth of the body seems to increase the irritation to the utmost pitch, and sleep becomes absolutely impossible. Rubbing or scratching the parts attacked merely intensifies the discomfort, the creature pushing itself deeper into the flesh. Most painful sores are the result if the greatest care is not taken. The one certain remedy seems to be to anoint the inflamed spots with vaseline. This substance not only soothes, but appears to destroy the bête rouge by stopping up its breathing pores. I have never succeeded in detecting the creature on the skin, but, when reading in or near an infested lawn, I have captured many by watching for the minute scarlet dots travelling over the white paper.

The damage done by ticks to cattle is undoubtedly very serious. According to observations by Leidy, the adult female tick is able to absorb 100 times its weight of blood, swelling during that time to an enormous extent. This food is rapidly changed into eggs. The adult male does not increase appreciably in size, but his demands upon the host have probably been greatly underrated. An account of tick-infested cattle in Queensland states that they were so completely covered that the branding-iron had to be burnt through the ticks before it was possible to reach the animals' skins. A case in Texas is mentioned where it was found impossible to lay a silver dollar upon the body of the animals without touching some ticks. Again in Texas, 100 full-grown ticks were collected from each ear of a pony, while many immature ones were left behind. The mere abstraction of blood must, in this case, be a very serious drain upon the system.

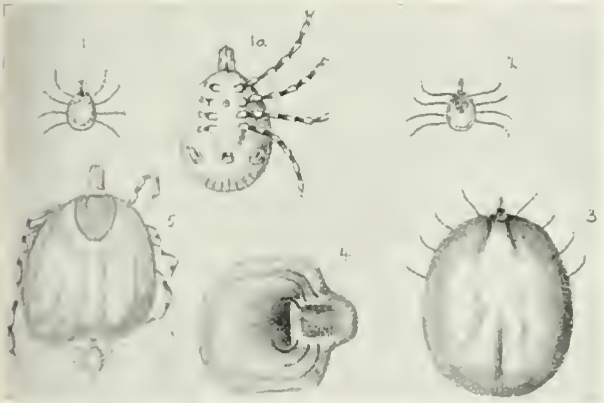
When one considers, further, the irritation experienced by travellers from the few ticks fixed upon them in their daily rambles, it may be safely concluded that the penetration of the countless proboscides into the skin of cattle must of itself be a source of great discomfort, especially as these animals are quite unable to get rid of them. Calves not uncommonly are destroyed by the formation of balls of hair in their stomachs; and in tick-regions this is undoubtedly due to an attempt to get rid of the parasites by licking and biting them off.

It is quite conceivable, then, that ticks do really cause the death of multitudes of cattle on the great estates where it is impossible to examine them closely. We should, however, approach this part of the subject with caution. Sickly cattle are usually covered by ticks, while the healthy ones have only a few; but it is questionable whether the ticks are the real cause of their emaciation. The case of ticks seems rather to be analogous to that of scale insects on plants. The latter pests appear in great quantities at any period of stress, when from lack of nutriment or other cause the plants become weakly. Thus, in Antigua, there is a marked disappearance of scale insects with the commencement of the rainy season. It seems probable that the prevalence of ticks upon certain cattle is rather due to conditions of the blood or skin of the animal, closely connected with its general nutrition. This is an exceedingly important matter for determination, for upon it, as will presently be shown,

depends the only means of freeing the cattle from these pests.

Thus far the direct effects of ticks upon cattle have been considered. Certain alarming facts have lately been brought to light with regard to the relations existing between ticks and different well-known cattle diseases. The subject is by no means new, having long been a fascinating one for cattle-breeders. The "louping-ill" or "trembling" of the north of Britain has been traced by some directly to the presence of ticks upon the sheep. The same may be said of a disease called "heart-water" at the Cape of Good Hope. Finally, the United States Department of Agriculture has for the last five or six years been conducting exhaustive experiments upon the connection between ticks and the Texas cattle fever, the results of which have appeared in the annual reports of the Bureau of Animal Industry already referred to.

There is, in this latter case, present in the blood of the cattle suffering from disease, an infusorian which quickly destroys the red blood corpuscles. This minute organism has also been detected in the body of the tick. It has been again and again transferred from diseased animals to healthy ones by means of the tick, and tick alone. The presence of this infusorian is regarded as diagnostic of



The Great Antigua Gold Tick.—*Hyalomma venustum*, Koch. (1) Mature male, natural size; colours, gold, scarlet, and black. (1*a*) Magnified ventral view. (2) Female, mature but not inflated; colours, shield black with flesh-coloured and gold spots; body dark green. (3) Female full of blood, natural size; colour, dark green. (4) The same female as in (3), after 20,000 eggs had been laid. (5) Female into which male had accidentally inserted his proboscis; both magnified.

the disease; and the effect of its corpuscle-destroying powers is seen all over the body, as well as in the red-coloured urine, which has won for the disease the colonial name of "red-water."

Ticks, then, are in certain cases connected with the transmission of deadly disease. In how many more cases this is so remains to be investigated. It is quite possible that some of the obscure cattle diseases in different parts of the world are caused by ticks, and that other countries will, in their turn, be forced to face this problem.

There is now and then an outbreak of a severe skin disease among cattle in Antigua; and this disease does not appear to be known in the neighbouring islands. Judging from the climate and peculiar conditions of Antigua, the scarcity of water and lack of nutritious food for part of the year might be considered sufficient to account for a local disease; but there is also a large tick present, which has not been recorded from the other islands of the group. A loose theory has thus arisen that this "gold tick" is connected with, if not the direct cause of, the cattle disease.

The evidence available does not tend to confirm this idea, but it is obviously impossible to solve the problem in the absence of proper appliances. I was led, however, to commence observations upon the gold tick, which may be of interest.

Mr. A. D. Michael has determined it to be *Hyalomma venustum*, which Koch described in 1847 from a single male specimen collected in Senegal. There is a local tradition in Antigua that the tick was introduced some thirty or forty years ago with some imported Senegal cattle; and this determination lends probability to the belief. The male is a very beautiful creature, decked in scarlet and gold, whence he obtains his name. The female is very large, one specimen being nearly an inch in length and weighing ·17 oz. I calculated the number of eggs laid by this female at over 20,000. She commenced laying on July 31, and finished, a shrunken mass, on September 10—a period of exactly six weeks. The accompanying life-size drawings are of Antigua gold ticks. The first is a mature male. He is not usually larger than this, and may be seen moving rapidly across the ground, or firmly attached to the skin of the cattle close to a female. The next three figures are of females, all mature, but at different stages. The first is undistended; the second gorged with blood, and commencing to lay its eggs; while the third is the same tick after the last egg was laid. There is also the drawing of a curious case, in which a male had by accident attached himself to a distending female—a mistake which resulted in the premature death of both.

The period of incubation observed in the tick's eggs varied from twenty-three to fifty-one days. The young ticks usually emerged in great numbers on the same day, and any eggs left unhatched quickly dried up. In Antigua the gold ticks appear upon cattle, in numbers, from May till September each year. It became important to determine what became of them in the meantime; and whether they passed the winter in the body of the parent, in the egg, or as young ticks. From experiments in the laboratory, it would appear that the little ticks pass the winter months huddled together in masses of several hundreds at the roots of the old dead grasses.

In considering the remedies for ticks, one is soon forced to the conclusion that direct measures against the parasite themselves will be of little avail. Methods of prevention are always preferable to those of cure, and in no case is this more so than with parasites of this class. Besides this, they are practically invisible at the most dangerous stage; and when we see the ugly, swollen, mature specimens, we know that their evil work is done. All large females should be carefully collected and burnt, however, as thus future attacks will be diminished.

The treatment of pastures is a very important matter. Here probably the parasite spends the greater part of his early life usually on the ragged bunches of old grass left from previous years. The proper feeding or cutting of the grass, and the liming and draining of the pastures, will destroy myriads of the infant ticks or "grass-lice." For the sake of the animals, there is every inducement to render the pastures as nutritious as possible; and ticks do not seem to trouble the sleek cattle of the herd. It is an undoubted fact, moreover, that the improvement in food, due to change of pasturage, does in certain cases cause all the ticks to drop off infested animals. The first class of remedies will aim at cutting off the supply of ticks by treating the pastures.

The second class—one might say almost the only one which is attempted in the tropics—is the destruction of ticks upon the cattle.

The common method of tying the legs of the animal together, hurling it to the ground, and smearing some tick-destroying compound over it, cannot be too strongly condemmed, especially as there is no need for it whatsoever. Cattle may be handled with impunity if some form of cattle-bail is employed; by this means they may be driven one by one into a small trap, where they

can be treated. But even this is hardly necessary if the application to the skin is in the liquid form; for with a powerful spraying machine, as many as one hundred cattle have been completely covered in the space of an hour.

Of pastes and powders and fluids recommended there is no end; and it will serve no useful purpose to give detailed lists discussing the merits of each. The points to be kept in view are that the liquid should be of an oily and non-poisonous nature, capable of clogging up the air-pores of the ticks. It should be cheap, and easily applicable without handling the cattle; it should, finally, not easily evaporate, or be washed off by the rains. A full discussion of remedies has recently been published by me, the following being taken from the summary at the end: "A number of types of washes for spraying are selected for description. All poisonous ones should be rejected, as there are non-poisonous preparations equally effective. Carbolic acid dips and other liquids, which evaporate quickly, need frequent applications, and should be discarded in favour of oily liquids or emulsions where the latter are equally effective. The best of all these is the kerosene emulsion regularly used for plants. There are many formulæ for the preparation of this; a useful one for ticks is given." The formula referred to is as follows: "In two quarts of boiling water dissolve half a pound of soap; remove from fire; immediately add one pint of kerosene, and agitate. In from three to five minutes the liquid becomes creamy. It may be stored in this form in bottles or barrels. For use, add three of water to one of emulsion; mix thoroughly, and apply with a spraying pump."[1]

The third and most important class of remedies is closely connected with the nutrition of the animal. If we can render the skin or blood of our cattle so distasteful to the tick that the latter will not attach itself, we have a solution of the whole matter. We should confer immunity upon our animals, and, at one stroke, do away with the necessity of all the laborious and expensive methods now in vogue for the destruction of these parasites.

The first step in this direction has been taken; and, in various parts of the world, most excellent results are recorded from the addition of small doses of sulphur to the animal's food.

It has already been noted that the food of animals has an influence upon their infestation by ticks. Cases are not uncommon among cattle-breeders where a mere change of pasture will cause all the ticks to drop off. This change is obviously felt through the animal's skin.

It has also been mentioned that the ticks seem to congregate upon cattle in poor condition, while those with sleek skins are more or less untouched. Dr. Cooper Curtice (late of the United States Bureau of Animal Industry) suggests, as an explanation of this, that there is in well-fed cattle an oily condition of the skin obnoxious to the ticks; and this suggestion is the more worthy of consideration when we remember the aversion of these creatures to grease of any kind.

It is certain that *sulphur taken internally* will render the skin evil-smelling, by the exhalation of sulphuretted hydrogen, a substance highly obnoxious to all parasites. The following seem to be the physiological changes which take place during the passage of the sulphur through the animal's body to the skin. Sulphur taken in with the food passes the stomach unaltered. In the intestines a small portion is changed into sulphides of hydrogen and the alkalies. Part of these sulphides pass into the blood, and into the tissues from the blood, and act chiefly upon the central nervous system. The sulphides in the tissues are variously excreted. By the kidneys they are excreted as sulphates; if in excess, part is also excreted in the form of sulphides. By the skin they escape as sulphides, giving the characteristic foul odour to the perspiration, and somewhat increasing its amount.

[1] For further details see paper in Leeward Islands *Agricultural Journal*, No. 1.

The doses of sulphur should be small, but they should be constant. The form in which the medicine is offered to the animals will best be decided by the manager of the estate. With stall-fed cattle there can be no difficulty at all; but with the cattle of large estates, which are seldom handled and sometimes not seen for long periods, it will be necessary to prepare the sulphur with salt as a "lick," to which cattle will readily help themselves if it is scattered about.

The success of this sulphur treatment has so far been encouraging, both at the Cape of Good Hope and in the United States. Doubtless with continued study other similar preventive remedies will from time to time be discovered, and thus rid the stockowners of the tropics of one of their most dreaded enemies.

C. A. BARBER.

NOTES.

PROF. HUXLEY'S health is at present a source of great anxiety to his friends. Symptoms of renal insufficiency appeared last week, and this, with the other complications which have attended his protracted illness, has made his condition a very critical one, but we are glad to learn that it is improving.

WE deeply regret to notice the announcement of the death of Dr. W. C. Williamson, Emeritus Professor of Botany in Owens College, Manchester. Dr. Williamson was elected into the Royal Society in 1854.

PROF. VERNEUIL, the eminent French surgeon, and Member of the Paris Academy of Sciences, died on June 12.

PROF. SIMON NEWCOMB has been elected Associé étranger of the Paris Academy of Sciences, in succession to the late von Helmholtz.

PROF. W. PETERSON, Principal of the University College, Dundee, has accepted the position of Principal of McGill University, Montreal, in succession to Sir William Dawson.

SIR E. MAUNDE THOMPSON, principal librarian of the British Museum, has been elected a Corresponding Member of the Philosophico-historical Section of the Berlin Academy of Sciences.

THE University of Pennsylvania has received gifts, within a few days, aggregating nearly a million dollars. This includes half a million dollars from Provost Harrison, already noted in these columns. Scarcely a week passes without our being able to record similar gifts from private benefactors to the universities and colleges of the United States. *Science* reports that Dr. D. K. Pearson has offered £10,000 to Mount Holyoke College if an additional £30,000 can be raised. It is said that Dr. Pearson has already given £400,000 to various colleges.

THE death is announced of Dr. A. Eliseief, known for his explorations and anthropological work.

THE St. Petersburg correspondent of the *Lancet* reports that the Emperor of Russia has appointed a committee to organise the collection of subscriptions for the monument which the Institute of France propose to erect to Lavoisier.

THE trustees of Columbia College decided, a few days ago, to grant the Barnard Medal to Lord Rayleigh and Prof. Ramsay jointly for their discovery of argon. Only Lord Rayleigh's name was mentioned in the previous announcement of the award.

DR. BACKLUND has been elected a Correspondant of the Paris Academy, in the Section of Astronomy, in the place of the late

M. Wolf: and Prof. Kowalewsky has been elected to fill the late M. Cotteau's place as Correspondant in the Section of Anatomy and Zoology.

The French Association for the Advancement of Science will meet at Bordeaux, from August 4 to August 9, under the presidency of M. E. Trélat. Applications for membership should be addressed to the Secretary of the Association, 28 rue Serpente, Paris.

The third international meeting of Psychologists will be held at Munich from August 4 to 7. The first meeting was held at Paris in 1889, and the second in London in 1892. Prof. Stumpf, of Berlin, will act as President, and Dr. von Schrenck-Notzing, of Munich, as General Secretary.

The second Italian Geographical Congress will be held in Rome next September, under the patronage of the King of Italy and the Duke of Genoa. The President of the Congress will be Marquis G. Doria, President of the Societá Geographica Italiana. The Secretary is Prof. D. Vinciguerra, and his address is Via del Plebiscito, 102, Roma.

Dr. T. G. Brodie has succeeded Prof. C. S. Sherrington, F.R.S., as Lecturer on Physiology at St. Thomas's Hospital.

Prof. E. Hering, of Prague, has been proposed as successor of the late Carl Ludwig in the chair of Physiology at Leipzig.

Prof. E. Mach, of Prague, well known by his book on Mechanics, and by his experimental researches on Physics, has been appointed Professor of Philosophy at the Vienna University. Vienna will, therefore, be the first place where Philosophy will be taught on a modern and scientific basis.

The Cracow Academy of Sciences offers prizes of 1000 and 500 florins for the best discussion of theories referring to the physical condition of the earth, and for the advancement of an important point connected with the subject. Memoirs must be sent in before the end of 1898.

The International Conference on the Protection of Wild Birds met at Paris on Tuesday, under the presidency of M. Gadaud, Minister of Agriculture. England was represented by Sir Herbert Maxwell, Mr. Howard Saunders, and Mr. F. Harford, of the British Embassy at Paris. Belgium, Holland, Germany, Russia, Austria-Hungary, Luxemburg, Switzerland, Italy, Greece, and Spain have also sent delegates. The conference meets as the result of a resolution passed at the International Agricultural Congress held at the Hague in 1891.

At the recent annual meeting of the Royal Society of Canada, the following officers (says *Science*) were elected for the ensuing year:—President, Dr. R. S. C. Selwyn, C.M.G., F.R.S.; Vice-President, the Archbishop of Halifax, Dr. O'Brien: Secretary, Dr. J. G. Bourinot, C.M.G.; Treasurer, Prof. J. Fletcher. Prof. Bovey, Dean of the Faculty of Applied Science, McGill University, was chosen President of the Section of Mathematical, Physical, and Chemical Sciences, Prof. Dupuis, Vice-President, and Captain E. Deville, Surveyor-General of the Dominion, Secretary. In the Section of Geological and Biological Sciences the following choice was made:—President, Prof. Wesley Mills; Vice-President, Prof. Penhallow; Secretary, Dr. Burgess.

At the annual general meeting of the Numismatic Society of London, held on Thursday last, Sir John Evans, President, in the chair, the silver medal of the Society was awarded to Prof. Theodor Mommsen, for his distinguished service to the science of Numismatics. Dr. Barclay Head, keeper of coins in the British Museum, in returning thanks on behalf of Prof. Mommsen, drew attention to the fact that quite recently Mommsen had handed over to the Royal Academy of Sciences of Berlin the sum of 25,000 marks, presented to him as a testimonial from his disciples in all countries on the occasion of the jubilee of his Doctorate, with directions that it should be devoted to the compilation and publication, under the auspices of the Academy, of a complete *corpus* of all known extant Greek coins.

Few neighbourhoods offer more features and objects of interest than the district around Galway. An excursion to this district, arranged by the Irish Field Club Union, will therefore probably be a very successful one. The country west of Galway presents the geologist with a great variety of rocks and rock structures. Some of the most interesting studies in Ethnography afforded in the British Isles may there be found, and the antiquarian and archæologist are offered exceptional attractions. The party will meet at Galway on Thursday, July 11, and will stay in the neighbourhood until the following Wednesday. The places to be visited are: The Twelve Bens, Connemara, Ballyvaughan and the Burren district, the Aran Islands, Oughterard and Lough Corrie. A programme, containing notes on the topography, geology, botany, zoology, ethnography, and archæology of these places has been prepared. During the reunion, a conference will be held for the consideration and discussion of matters relating to the advancement and extension of Field Club work in Ireland. The Secretary of the Union is Mr. R. Lloyd Praegar, National Library, Dublin.

It has long been known in a general way that the time required for hatching out the eggs of cold-blooded animals is dependent on the temperature at which they are kept; and that in the case of birds "the period of incubation is much related to the size of the bird." Mr. A. Sutherland (Roy. Soc. of Victoria, December 1894) has recently made some observations on the relations between hatching-time and temperature, and formulates a law based upon his results. He has further investigated incubation among birds and gestation. Birds and mammals keep at a practically constant temperature—between 37° C. and 43° C.; and it may be assumed that sitting birds keep their eggs at a tolerably definite temperature. Why then should the period of incubation or gestation vary so much? Mr Sutherland asserts that the time of incubation or gestation, as the case may be, has a certain definite relation to the weight of an animal. He states the two laws he has arrived at in the following words:—(1) "For animals of the same size the time of embryo development is inversely proportional to the square of the temperature, that temperature being reckoned from a definite point." (2) "At the same temperature, the period of development is directly proportional to the sixth root of the weight of the mature animal."

A few months ago, M. de Montessus published an interesting paper on the frequency of earthquakes, of which a summary is given in a previous note (vol. li. p. 540). This he has followed up by another paper of still greater value on the relation between seismic frequency and the relief of the ground (*Comptes rendus*, vol. cxx. pp. 1183-1186). The following are the general conclusions at which he has arrived from a study of 348 regions, in which 9700 earthquakes and 5000 volcanic eruptions are known to have occurred. In a group of adjoining districts, the most unstable are those which present the greatest differences of relief, *i.e.* those whose average slope is greatest. The unstable regions follow the great lines of folding of the earth's crust. Mountainous countries are generally more unstable than flat ones, and, in any one mountain-chain, the

short and steep slope is the more unstable of the two, especially in its steepest parts. Coast regions with a rapidly deepening sea are unstable, especially if bordered by an important mountain-chain: those with a slightly sloping sea-bed are stable, especially if they adjoin a flat country. Lastly, in regions which are frequently disturbed by earthquakes, and which at the same time possess very active volcanoes, the seismic frequency and volcanicity are independent. It follows, therefore, that earthquakes are a purely geological phenomenon, and probably have their origin in the same dynamical forces to which the present relief of the earth's crust is due.

RADIOLARIAN earth of Tertiary age has long been familiar from Barbados: in a recent number of the *Bull. Museum Comp. Zool.* (Harvard), Mr. R. T. Hill records it from the island of Cuba. It occurs at one place only, near Baracoa, where it is over 500 feet in thickness and is well stratified, the strata being vertical. The rock is chalky in appearance, with occasional thin separation-layers of a grey-blue clay, and some flint-like siliceous nodules: sponge-spicules and echinoid fragments were found in it, but no diatoms. It appears to lie below certain yellow beds identified as Miocene. The paper contains much other information on the geology of Cuba, and the origin of the circular harbours of the north coast is dealt with. The author finds no evidence of any movement of depression in the island since the beginning of Tertiary times.

DR. F. KLENGEL, of Leipzig, has sent us a copy of his paper, read some time since before the Bohemian Society of Sciences, on the non-periodical variations of temperature in the district of the Pic du Midi and Puy de Dôme, compared with those at St. Bernard, for which station a longer series of observations is available. The problem undertaken by the author was mainly to show how far the irregular variations of temperature in these three widely separated and high regions of Central Europe agreed together. The most important conclusions drawn from various tables are, that a remarkable agreement is shown in the non-periodical changes at the mountain stations, whereas in the plains the variations differ materially from each other. The influence of the sea is visible in the lower region of of the Pic du Midi, but at the higher level it entirely disappears.

THE papers in the June *Journal* of the Royal Microscopical Society include one on British patents taken out in connection with the microscope, between 1666 and 1800.

THE Department of Mines of Victoria has issued a report on the Victorian coalfields, the development of which is proceeding rapidly. Evidence is given to show that the coal is of drifted origin: among other points, the mixture of conifers and ferns in the flora can only be explained by transport before deposition.

MR. JOHN TEBBUTT has sent us a report of the work done at his observatory, Windsor, New South Wales, during 1894. Meteorological observations have now been made at the observatory for thirty-two years. Among the astronomical work of last year were observations of lunar occultations of stars, of southern comets, and of double stars.

THE sixty-first annual report of the Natural History, Literary, and Polytechnic Society of York School gives evidence of enthusiastic work in many branches of science. Few school societies of a similar kind can boast of reports running into the sixties. With this report we received the *Natural History Journal* and *School Reporter* for June 15, conducted by the societies in Friends' schools. The journal contains articles on Southern Tyrol and on the planet Mars, as well as notes, and records of observations of scientific interest.

Bulletin No. 48 of the U.S. National Museum is devoted to "A Revision of the Deltoid Moths," by Prof. John B. Smith, the paper being a contribution towards a monograph of the insects of the Lepidopterous family Noctuidæ of Boreal North America. Fourteen plates, showing the different species of these Noctuids, and the structural characters of the Heliini, Herminiini, and Hypenini, accompany the descriptive text. The genera Pseudorygia and Rivula are not included in the series, Prof. Smith being of the opinion that they do not possess real Deltoid characteristics.

THE Report of the Geological Survey of Canada for 1894 describes the results of geological expeditions in the Labrador Peninsula and west of Hudson Bay. In consequence of lack of money it was found necessary to reduce the number of parties working in the field, while there is an accumulation of material awaiting publication. A deep boring for petroleum has been begun at Athabasca Landing, but at a depth of 1011 feet the oil had not been reached: all indications, however, point to the existence of great quantities of petroleum in the Devonian strata which immediately underlie the Cretaceous.

THE Central Physical Observatory of St. Petersburg has made an important addition to its comprehensive *Monthly Weather Report* by showing on a chart the deviations of temperature and rainfall of the month from the normal conditions. To arrive at this, M. Wild states that the values have been calculated for no less than 322 stations, all of which are represented in the report. The excess or defect of temperature at each place is shown on the chart by drawing curves through those places where the deviation is equal in amount, while the deviation of rainfall is represented by red and blue tints. The work is very neatly executed, and shows clearly, at a glance, the climatic conditions of the month.

THE 1895 *Photography Annual*, edited by Mr. Henry Sturmey, is an invaluable compendium of photographic information, and a useful record of the progress made during last year in the various branches of the science and practice of photography. In it Mr. C. H. Bothamley traces the advances of photographic chemistry; Mr. Chapman Jones describes the work done in the field of photographic optics; Mr. T. Bolas records the progress made in photo-mechanical printing; Captain Abney writes on spectrum photography; and Mr. Albert Taylor contributes a very full account of what was done in astronomical photography during 1894. These records, together with descriptions of new photographic apparatus and materials, technical articles, and particulars of photographic societies throughout the United Kingdom, render the *Annual* indispensable to all who take an intelligent interest in photography. The publishers are Messrs. Iliffe and Son.

THE current number of the *Comptes rendus* contains an account, by M. Berthelot, of a new combination of argon. Following up his researches on argon, this author has discovered that free nitrogen, prepared pure from nitrites, can be caused to enter into combination with the elements of carbon disulphide when subjected to the spark or silent discharge after saturation with disulphide vapour. The resulting compound contains some mercury sulphocyanide, and does not regenerate nitrogen under the action of heat or of concentrated sulphuric acid. When argon is employed in place of nitrogen, a similar reaction appears to take place. Under the continued action of the silent discharge, a sample of 6·55 c.c. of argon, as pure as it could possibly be obtained, saturated with carbon disulphide vapour

at 20° C., and confined in the reaction tube by mercury, gave a continuous absorption which appeared to go on indefinitely. The product contained mercury, but gave no reaction for sulphocyanide. When heated, a quantity of gas was recovered equal to about one half the volume absorbed, and this recovered gas was proved to be argon by condensation with benzene, and production of the remarkable fluorescence previously described. Though this work has been done on such small quantities of material that an exhaustive examination of the product was not possible, M. Berthelot believes that he has satisfactorily demonstrated the significant property of argon, that it can enter into combination and be regenerated from its compound or compounds with its initial properties intact.

As a result of observations carried on by the *Investigator* in the autumns of 1892-3-4, Commander C. F. Oldham, R.N., contributes two papers on the Laccadive Islands to the *Journal of the Asiatic Society of Bengal* (vol. lxiv. pt. ii. No. 1, April 1895). The group consists of four submerged coral-reefs, six reefs with small islets ("sand-cays"), and eight inhabited atolls: three of the reefs and five of the atolls were examined. The islands and sand-cays occur, in all cases but one, on the eastern side of the atolls; they cannot, therefore, have been built up by the action of the ordinary monsoon winds which blow mainly from the west, but must be due to the occasional hurricanes which reach the eastern and north-eastern sides of the atolls. The effect of the tides and currents is seen in the more vigorous growth of the atolls to the south and west. The islands and islets are extending at their extremities, and in some cases are being added to on the south-western sides where they face the lagoon. No evidence of either elevation or subsidence was observed.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mrs. Stevens; two Javan Parrakeets (*Palæornis javanica*) from Java, presented by Lieut.-General Sir H. B. Lumsden; a Green-winged Trumpeter (*Psophia viridis*) from Brazil, presented by Mr. H. A. Astlett; a Diamond Snake (*Morelia spilotes*) from Australia, presented by Mr. M. Mitchener; a Natal Python (*Python natalensis*) from South Africa, presented by Mr. William Norman; a Korin Gazelle (*Gazella rufifrons*, ♀) from Senegambia, a Blue and Yellow Macaw (*Ara ararauna*) from South America, a Naked-necked Iguana (*Iguana delicatissima*) from Tropical America, thirty-four Black Salamanders (*Salamandra atra*), South European, deposited; a Tachiro Goshawk (*Astur tachiro*) from South Africa, nine Red-beaked Weaver-Birds (*Quelea sanguinirostris*) from West Africa, purchased; a White-crested Jay Thrush (*Garrulax leucolophus*), a Striated Jay Thrush (*Grammatoptila striata*) from India, received in exchange; a Burrhel Wild Sheep (*Ovis burrhel*, ♀), a Patagonian Cavy (*Dolichotis patachonica*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE YERKES OBSERVATORY.—From a note in the *Astrophysical Journal* for June, we learn that the construction of the buildings of the Yerkes Observatory is advancing rapidly, and it is hoped the 40-inch refractor will be ready for use in September or October. The Observatory is situated on the shores of Lake Geneva, Wisconsin, at an elevation of 180 feet above the lake, and is about seventy-five miles from Chicago. The dome for the great telescope, which is being built by Warner and Swasey, is 90 feet in diameter, with a shutter opening 12 feet; the rising floor is 75 feet in diameter, and will have a vertical movement of 22 feet. The motive power for turning the dome and elevating the floor of the Observatory will be supplied by electro-motors.

In addition to the large telescope, provision is made for the use of the 12-inch telescope now at the Kenwood Observatory, and another telescope of 16 inches aperture. The meridian room is designed to accommodate a large meridian circle, but, in the first instance, a transit instrument will be employed.

The Observatory buildings appear to be designed on a very liberal scale, and comprise offices, library, lecture theatre, spectroscopic, physical, chemical, photographic, and other laboratories. We understand that Prof. Barnard and Prof. Burnham have accepted positions in the Observatory.

THE GRANULATION OF THE SUN'S SURFACE.—The granular or mottled appearance of the surface of the sun is familiar to all observers, and the great resemblance to terrestrial cirrus clouds has long been recognised. A possible cause of this appearance has been recently suggested by Dr. Scheiner (*Astr. Nach.* 3279), the idea being that Helmholtz's investigations on the formation of waves in our own atmosphere apply also in the case of the sun. According to Helmholtz, air waves are produced when two strata of air of different temperature and density glide over each other; if the lower layer is nearly saturated with aqueous vapour, the wave crests will be centres of condensation, in consequence of diminished pressure, and will appear as clouds, while the depressions will form transparent interspaces. On this theory a "mackerel sky" is produced when two series of waves cross each other. Dr. Scheiner points out that somewhat similar conditions prevail in the sun; there are layers of different temperature, and currents in various directions in these layers, and in the photosphere the condensable gases are in an over-saturated state. He therefore considers that the bright grains of the photosphere are wave-crests of two crossing systems of waves, rendered visible by an increase of condensation. In the case of the sun, the observed lengths of the waves—that is, the distance between the separate grains—is from 1000 to 3000 kilometres, and it is believed that waves of this magnitude might be produced without the assumption of extraordinary velocities.

Assuming this to be a true explanation, the photosphere must be a very thin layer; and since the granules are of about the same size in all parts of the surface, the velocity of the currents must be nearly equal in all heliocentric latitudes.

THE SATELLITES OF JUPITER.—Not contented with his brilliant discovery of a fifth satellite to Jupiter, Prof. Barnard has been employing the great resources of the Lick telescope in further investigations of the satellites which were discovered by Galileo (*Monthly Notices, R.A.S.*, vol. lv. p. 332). One part of his work has consisted of micrometric measurements of the diameters of the satellites, and the results, reduced to a mean distance of the planet from the sun equal to 5·20, are as follows:

	Angular diameter. ″	Diameter in miles.
Satellite I. ...	1·048 ...	2452
,, II. ...	0·874 ...	2045
,, III. ...	1·521 ...	3558
,, IV. ...	1·430 ...	3345

It is pointed out that these values are in good accordance with the mean values derived from nine sets of measures made by as many different observers since 1829. Of the earlier estimations, those made by Schroeter in 1798 agree most closely with modern results.

Special attention appears to have been given by Prof. Barnard to Satellite I., on which he discovered, with the 12-inch equatorial, on September 8, 1890, the existence of a bright equatorial belt and dark polar caps. These appearances have been verified at every favourable opportunity, and "they are, beyond question, permanent features of the satellite, and will always be visible when a favourable transit occurs." These markings on the satellite fully account for all the phenomena which have been reported of the distortion or ellipticity of its disc, as well as for the apparent doubling of the satellite during some transits. When the satellite is transiting over a dark part of the planet, the white belt appears very prominently, while the dark poles are correspondingly difficult to see, so that, without very close attention, the satellite looks like a thin white strip. If, on the other hand, it be transiting across a bright part of the planet, the white belt is lost in the bright background, and the polar regions appear as two separate dark spots, making the satellite appear double. The dark polar caps are darkest at the poles, and become rapidly less intense towards the equator. Prof. Barnard considers that the phenomena observed on this satellite indicate that its physical condition is similar to that of Jupiter.

THE SUN'S PLACE IN NATURE.[1]

VII.

AT the end of the last lecture, some evidence was brought forward which leads to the conclusion that in those stars in the spectrum of which bright lines are seen, we are dealing with bodies closely associated with nebulæ. It was at once suggested

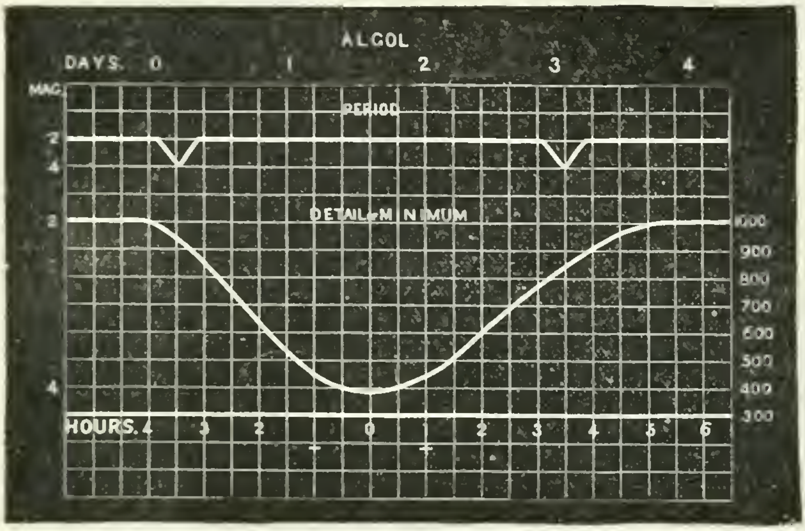


FIG. 2.—Light-curve of Algol.

that possibly by those new methods of inquiry to which I have already referred, we might be enabled to demonstrate the existence of the nebulæ, although we can never hope to see them by the unaided human eye. The idea occurred to me that long exposed photographs might give us stars surrounded by nebulæ. So I wrote to Dr. Roberts, who always kindly places himself at the disposal of any student, and asked him if he would be so good as to photograph that region of the heavens in which most of the bright-line stars have been observed. He at once acceded to my request, and took photographs, as desired, with his instrument, giving an exposure of three and a quarter hours. The result a little disappointed me, because he reported that there was no indication whatever of any nebulosity surrounding these stars. Possibly it was on this account that Dr. Huggins felt himself justified in objecting to the view which associated these stars with nebulous surroundings. But that is not the whole story. Some time afterwards, at the request of Mr. Espin, Dr. Max Wolf, who has an instrument which is even more competent to pick up faint details than the wonderful telescope employed by Dr. Roberts, took photographs of this same region; and I need not tell you that, being anxious to carry the inquiry as far as he could, he made the exposure what we should consider almost impossibly long—so long, in fact, that one single night was not sufficient. His first photograph of this region was exposed for thirteen hours on three nights; the next one was exposed for eleven hours. Now I will throw on the screen the result which was obtained by Dr. Wolf with the instrument which at the present moment is the most competent to give a verdict upon such inquiries as this. Here, in the first instance, we have a photograph of the region surrounding the brightest star in the constellation Cygnus, and you will observe that we have here and there indications of nebulous matter as well as of stars. That is rendered evident by the fact that in certain other regions we get a perfectly flat background, whilst in this the background itself is luminous. Now we come to the region in which these bright-line stars have been recorded for several years, and you see it is almost impossible to point out in this photograph a large area in which there is not a most obvious indication of this luminous nebulosity. Patches here and there seem to indicate that the great differentiation between this part of the sky and others, lies not in the wealth of stars, but in the wealth of the luminosity in which they are situated.

It was obvious therefore, from this experiment, that I was perfectly justified in stating that these bright line stars were associated with nebulæ, since we find the statement made on theoretical grounds now backed up by these exquisite data, which indicate that most certainly there is a complete association of nebulous matter with these stars.

I do not want to part with that diagram until I have pointed out to you the enormous advantage students of science now have in possessing such magnificent photographs as these. Not only is the wealth of science rendered obvious, but the wealth of nature. Here, you see, is what modern science makes of a little patch of the sky on which the naked eye sees nothing at all.

The conclusion is therefore this: there seems to be no doubt that bright-line stars are directly connected with nebulous matter. I am glad to add that this is also the conclusion of the American astronomers who have inquired into the subject.

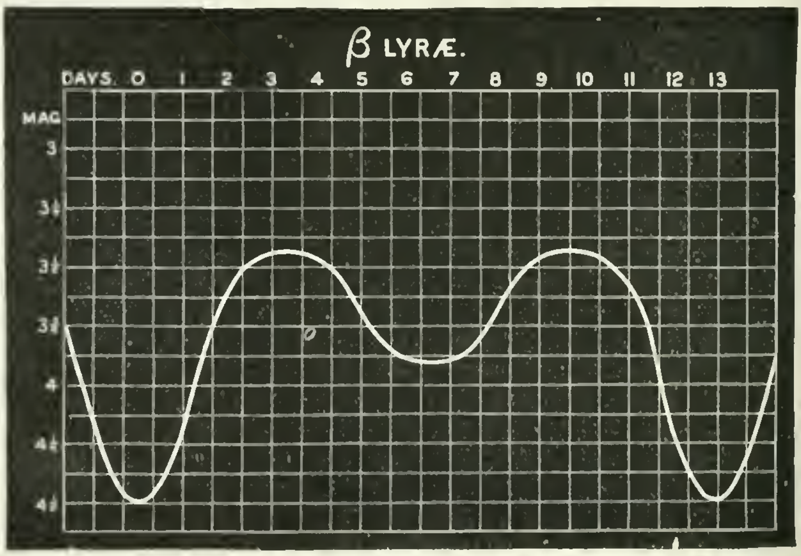

FIG. [illegible].—Light-curve of β Lyræ.

The next point in the meteoritic hypothesis—that some of the heavenly bodies are increasing, others diminishing their temperature—is one which I have brought out in that strong form, but I do not propose to say very much about it to-night. You may remember what has been said with reference to the hypothesis of Kant and Laplace, and especially Laplace's view that in the nebulæ we have to deal, as also in the stars

[1] Revised from shorthand notes of a course of Lectures to Working Men at the Museum of Practical Geology during November and December 1894. (Continued from page [illegible].)

associated with them, with gases at a very high temperature. Now, in the hypothesis which I have ventured to put before the world of science, I differ in this particular both from Laplace and also from Vogel, who has most industriously attempted to establish a classification of the celestial bodies. I pointed out that in accordance with thermo-dynamical principles, the temperature must increase with condensation, and of course it will depend, therefore, upon the condensation of the gas, whether we have to deal with high or low temperatures in the bright-line stars and the nebulæ. I wish to take this occasion to state that Prof. Darwin has recently shown, as the result of a most profound inquiry, that swarms of meteorites in space will behave exactly like a gas; therefore, what can be said of the thermo-dynamics of a gas may be said also of the thermo-dynamics of a meteoritic swarm.

Now we come to a very interesting part of the inquiry, because it lands us among phenomena which so far have been considered to be exceptional. I refer to the phenomena of the so-called variable stars. You will see in a moment that if there is any truth in what has been brought before you, the light of stars as they pass from the nebulous to the more luminous stage must change during the progress of that evolution. But remember, that change will not be visible to one generation of men, probably not to a thousand generations of men. It is a change which will require millions, and possibly billions, of years for its accomplishment; and therefore we must not associate the word "variable" with any change which depends wholly upon the evolution of these various stellar conditions. But in addition to that, we can see almost in hours, certainly in days, frequently in months, sometimes in years, changes in the light of certain stars: and it is these short period changes which mark out and define for us the phenomena of variable stars.

Take a star like the sun. It is pretty obvious to you that any change in the sun, such as we see it now, would require a very considerable time for its accomplishment, so as to be obviously visible to us all: but if you take two bodies like the sun, you might imagine a condition of things in which one body would come exactly in the line between the earth and the other body, and would so eclipse the further one. There you have at once the possibility of an eclipse due to the passage of one body in front of another, and therefore of a variability which depends upon eclipses. So much for two bodies like the sun; but we know that in various parts of celestial space some of the stars have run through their life of light, and exist as dark bodies. Obviously we should get the same eclipse phenomena when dealing with one star like the sun and another dark body, provided always that the dark body came and eclipsed the light one. That is a very well known and accepted cause of variability, and one of the most obvious cases of this kind we have in the star Algol. There we have two bodies, a bright and a dark one, and a diagram will give us what is called the light-curve, the curve indicating the variability brought out by such a condition as that I refer to. When we come to examine the light-curve of a body like this, we find that the luminosity of the star remains constant for some considerable time in relation to the period of variability, and then it suddenly decreases. It almost at once—in an hour or two—goes up again, continues then for another period, and suddenly diminishes again (Fig. 29).

Spectroscopically we can inquire into the question as to whether there is or is not any physical change connected with this. Obviously, if it is merely an eclipse, there should be no physical change, and therefore no change in the spectrum. Here, by the kindness of Prof. Pickering, I can show you two photographs of the spectrum of this star, when it is most luminous, and when it is least luminous, and the spectra of these two conditions are, you see, quite similar. The broad lines are alike; in other dark lines also there is no change. Therefore, spectroscopically, we are justified in saying that the theory that variability is caused by eclipses is a perfectly justifiable one.

But supposing we consider no longer two bodies like the sun, or even one sun and another body more condensed and colder than the sun, but two not completely condensed meteoritic swarms; various probabilities never before considered will lie open to our inquiry.

We may take the remarkable case of variability presented to us by one of the brighter stars in the constellation of the Lyre, β Lyræ. The spectrum of that star has been very carefully studied, and if you will look at the details now on this diagram, you will see a series of the most marvellous spectral changes showing at once that we are not in the presence of phenomena at all similar to those presented in the last star examined. Fig. 30 shows the light curve of β Lyræ, which when at its lowest brightness is a $4\frac{1}{2}$ magnitude star, and at its greatest brightness is a $3\frac{1}{2}$ magnitude star, the changes going through one magnitude. In this scale you see that the changes are run through in a period of thirteen days. From the period of the greatest obscuration of

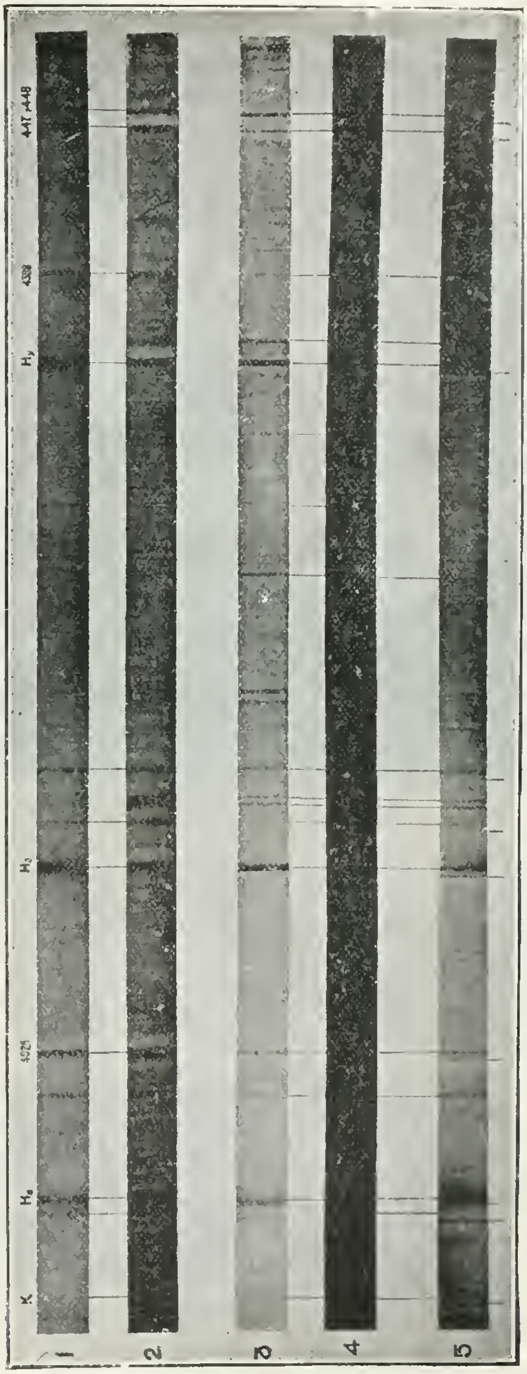

FIG. 31.—Spectra of β Lyræ (2, 3, 5) compared with Bellatrix (1) and Rigel (4).

light, in nearly three days we get to the highest luminosity, then at the sixth day we get to what is called a secondary minimum, *i.e.* the light has gone down a bit, but not so much as it had done at the beginning of this light cycle: then it goes up again, so that on the tenth day we get a maximum of light such as we had on the third day: after that it goes down, so that on the

thirteenth day, or thereabouts, we get to another minimum, and then the cycle begins again. Associated with these changes we have considerable changes in the spectrum. We have been fortunate enough to get a spectrum of this marvellous star for every day included in this period of change, although of course the photographs have not been taken in a period of thirteen days or in ten periods of thirteen days; but by knowing this period, we have been able to place the different photographs

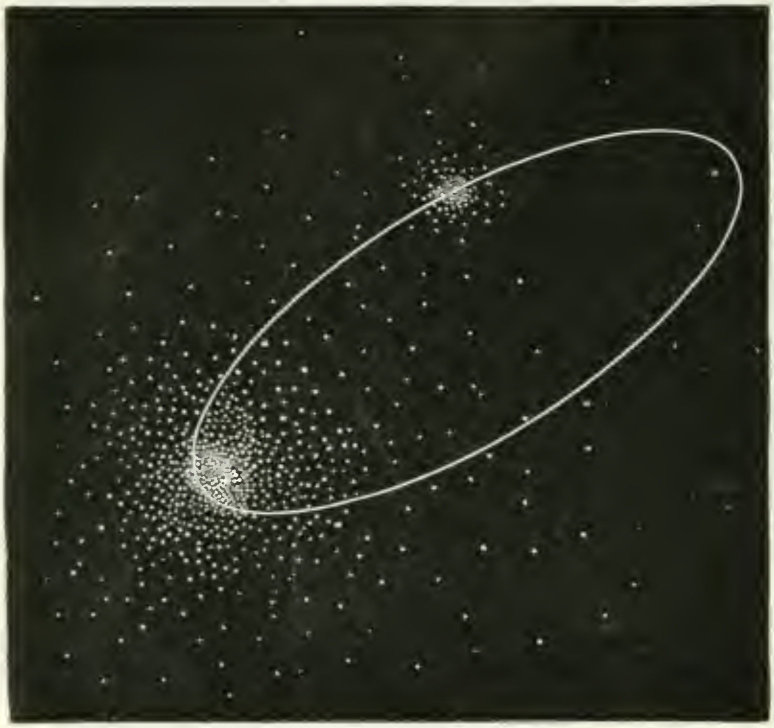

FIG. 32.—Cause of variability in uncondensed swarms.

together so as to see exactly what happens. We get bright lines and dark lines, and bright lines changing their places; but the main point we have been able to make out so far, is that we are dealing with two stars very much like a number of stars that we see in the constellation of Orion. In Fig. 31 we have photographs of the spectra of two of the stars in the constellation of Orion, and associated with them, three photographs of the spectrum of β Lyræ; from the change in the position and coincidence of these lines we are able to make out that the

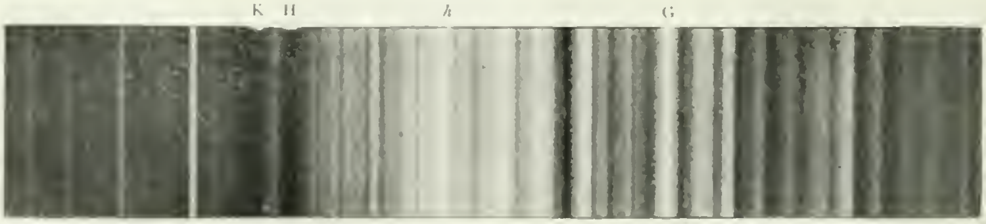

FIG. —Spectrum of o Ceti (Pickering).

variability of β Lyræ is produced by the revolution round each other of two stars like certain stars in the constellation of Orion, and that part of the light is probably cut off by some kind of eclipse; also that a certain amount of light which writes out for us these bright lines is produced at a certain part of the light curve. The photographs show that about the time of principal minimum, the dark line spectrum of β Lyræ (2) is very similar to that of Bellatrix (1), while about the time of secondary minimum the spectrum of β Lyræ (3) becomes more like that of Rigel (4), the differences at these times being mainly in the intensities of the lines. The photograph of the spectrum about the time of second maximum (5) shows that there are two spectra displaced with respect to each other. The spectrum displaced to the less refrangible side is shown to resemble that of Rigel, while that displaced to the more refrangible side closely resembles Bellatrix. I do not profess for one moment to imagine that all the conditions of variability in that star have been thoroughly explained, but we know enough to say that it is something quite different from the condition which obtains in such a star as Algol. Also, from the fact that we are dealing with stars like those in Orion, we know that we have to do with more or less condensed bodies, bodies not so condensed as the sun is, but still condensed enough to be called stars without fear of making any great mistake.

But in this class of condensed bodies we have only really touched one part of the subject, because if that condition holds for bodies which are condensed, it will not have held good for them and for others when they were less condensed than they are now. How, then, can we explain the variability of uncondensed swarms? Fig. 32 shows this.

Here we are dealing with two swarms so sparse that they may be almost considered as nebulæ; and we will suppose that round the denser and larger one a smaller one is moving in the orbit represented on the diagram. You will see that for a considerable part of the orbit the smaller swarm can perform its movement along the orbit without any chance of running up against any of the constituents of the greater swarm; but when that little swarm has got to go round what is called the periastron, *i.e.* the region nearest the centre of gravity, which is occupied by the densest portion of the primary swarm, it is impossible that it can get through without a considerable number of collisions between its own constituents and the constituents of the majority (I am not talking politics). What will happen? You will get light and heat produced, forming a variable star, which will give the greatest amount of light when those two swarms are closest together, and the least amount of light when they are furthest apart.

You can imagine also, that, instead of dealing with a highly elliptic orbit such as imagined in Fig. 32, we may have one in which the main mass is very much nearer the centre of the orbit of the smallest swarm, that orbit being much more circular than in the former case. There you will get a chance of a greater number of collisions in one part of the orbit than in another; but there will not be anything like so great a difference between the number of collisions at the two ends of the major axis of the orbit as there would have been in the first case supposed. In that way, therefore, we can explain the variability of these uncondensed swarms, and not only the variability, but a very considerable difference in the time of the cycle occupied by the changes and in the intensity of the greatest

light produced. So much is that to be anticipated, that I predicted in 1888 that when we got any indications of stars the spectra of which showed that they were really sparse swarms, such as that depicted on the diagram, at the maximum of their luminosity we should get bright lines, and in all probability bright lines of hydrogen, visible in their spectra. It so happened that shortly after this prediction was made—and when a man of science predicts he does it chiefly not for the sake of influencing others, but to point out where the path of truth really lies—I, in common with many other students in this country, received from Prof. Pickering a photograph of the spectrum of that most wonderful of all variable stars, commonly called Mira, or the marvellous star (Fig. 33). We knew before we received the photograph what its spectrum would in all probability be, but the interesting point was to see whether or not there were any bright lines in it. You see there is an obvious bright line at that part of the spectrum which represents the wave-length of one of the hydrogen lines; there is another where the wave-length of another hydrogen line is represented, and there is another very obvious bright line in another part of the spectrum. So that this photograph entirely justifies the prediction that had been made with regard to this class of stars. And so well is that now recognised that, quite independent of the meteoritic hypothesis, one of the most characteristic features of this class of stars is acknowledged to be the appearance at the top of the light curve—at the moment of the greatest giving out of light—the bright lines of hydrogen and possibly of other substances in the spectrum. Forty old variables of this class show bright lines, and twenty new variables have been detected by the appearance of bright lines, *i.e.* bright lines being seen in them suggested that they were variable, and a further inquiry into the old records showed that undoubtedly their light had varied.

J. Norman Lockyer.

(*To be continued.*)

THE INSTITUTION OF NAVAL ARCHITECTS.

THE summer meeting of the Institution of Naval Architects has been held this year in Paris, and has proved one of the most successful gatherings of the kind it has ever been our good fortune to attend. It had become known amongst members for some time past that a very strong Reception Committee had been formed, consisting of many French gentlemen, eminent both in the scientific and naval world. A large part of the week devoted to the meeting was given up to purely pleasure excursions and entertainments. Of these it is not within our province to speak, but it would be ungracious on the part of any English journal, dealing with the meeting in any way, not to say a word in recognition of the generous hospitality so lavishly displayed by all those connected with the organisation of the programme in France.

There were three sittings for the reading and discussion of papers; Lord Brassey, the President of the Institution, taking the chair on each occasion. Members assembled for the first time in the new amphitheatre of the Sorbonne, which had been kindly placed at the disposal of the Executive by the Rector of the University of Paris, M. Octave Gréard. Vice-Admiral Charles Duperré, President of the Reception Committee, welcomed the members, and Lord Brassey responded in a brief address.

The following is a list of the papers set down for reading and discussion on the programme.

"The Amplitude of Rolling on a Non-Synchronous Wave," by Émile Bertin, Directeur des Constructions Navales, and Directeur de l'École d'Application Maritime.

"On Wood and Copper Sheathing for Steel Ships," by Sir William White, Director of Naval Construction, and Assistant Controller of the Navy.

"The M.G. Metre," by Archibald Denny.

"On the utility of making the calculation of the total external volume of ships, and of drawing out the complete scale of solidity, from the triple point of view of tonnage laws, stability and load-line," by V. Daymard, Engineer in Chief of the Compagnie Générale Transatlantique.

"On Light Scantling Steamers," by B. Martell, Chief Surveyor Lloyd's Registry of Shipping.

"On Coupling Boilers of Different Systems," by Pierre Sigaudy, Engineer in Chief of the Forges et Chantiers de la Méditerranée.

"On the Cost of Warships," by Francis Elgar.

"On some necessary conditions for resisting intense firing in water tube boilers," by Augustin Normand.

"On the Niclausse Boiler," by Mark Robinson.

M. Bertin's paper, which was the first to be read, treated a highly technical subject from a strictly mathematical point of view. The author pointed out that perfect synchronism between the period of rolling and of the wave is practically a purely theoretical case. He referred to the latest calculations made which bear upon a large number of particular cases, and also to the principle of the graphic method, which has been previously described, and which is a simple extension of the method employed to determine the amplitude of rolling on a synchronous swell. The subject is one of extreme interest, but we fear we must refer those of our readers who are not acquainted with it to the published paper in the volume of the "Transactions" of the Institution. It would be impossible to give an abstract of M. Bertin's mathematics, or, indeed, to make the matter clear without the diagrams which accompanied the paper. One result, however, which may be quoted, is that M. Bertin confirms the facts brought out by Sir William White as to the great increase of efficiency of bilge-keels in large as compared with small ships. This, as our readers are aware, came somewhat as a surprise to those engaged in these matters. M. Bertin states: "We find, therefore, in bilge-keels a more powerful method of checking heavy rolling than has been foreseen. In a different condition of things, free liquid provides a more rapid means of extinguishing small rolls than could have been foreseen from any calculations founded on the known properties of liquids." M. Bertin states that the question upon which he treats is one that cannot be solved by calculation; accurate observations made at sea are the necessary complement of all the theoretical researches and experimental study made in port.

Sir William White opened the discussion on this paper. It will be remembered that at the spring meeting of the Institution the Director of Naval Construction was unable to be present, owing to a very severe illness. In spite of this, a paper which he had written on the subject now under consideration was read in his absence. His reappearance at the meetings was the occasion of a very general outburst of enthusiasm on the part of the members present, for no one is more popular, and indeed few have done more for the Institution, than Sir William White. Sir William pointed out that for mathematical purposes it was necessary to make assumptions which could be corrected by and applied to practical work. He paid a handsome compliment to the author by coupling his name with that of the late Mr. Froude.

The next paper read was Sir William White's own contribution on sheathed ships. This, as the author pointed out, was a direct contrast to the paper last read, being of a simply practical nature. As is well known, the purpose for which steel vessels of war are sheathed with wood, is in order that they may be coppered, and their bottoms may thus be preserved from fouling. It is needless to say that the wooden planking is applied as a means of preventing galvanic action between the copper and steel. In order to effect this, it is necessary that the planking should be water-tight, for sea water, in contact both with the copper and the steel skin, would set up galvanic action. It may be stated, however, in passing, that if the sea water is not in circulation, the galvanic action will not be intense or continuous, which is a fact that might be anticipated. In order to make the planking water-tight, it was originally thought necessary that a double skin should be used, and very elaborate precautions were taken in regard to fastenings. Sir William White, then Mr. White, came to the conclusion that the double planking was unnecessary, and that with proper care a single skin could be made to answer the purpose required. In this he was opposed by a large number of eminent authorities, but having the courage of his convictions, he introduced the new system into Her Majesty's Navy. The result has justified his anticipations, for after several years' experience, the hulls of ships thus sheathed have not been found to suffer.

Mr. Archibald Denny's paper described a small instrument he has invented by which the metacentric height of a vessel can be ascertained. It is intended for the use of captains of ships, so that they may ascertain the stability of their vessels under various conditions of load and trim. The instrument is simply a spirit-level pivoted at one end and adjusted at the other, by means of a micrometer screw. This combined with a diagram gives the value M.G. The method of using the instru-

ment is given in detail in the paper, and is made clear by means of diagrams.

M. Daymard's paper was of a commercial rather than a scientific interest. We all recognise that our tonnage laws are anomalous. Unfortunately they have become so interwoven with our commercial system, that it would require nothing less than a revolution to reduce them to a common-sense standard. M. Daymard commands our admiration by his courageous attempt, but as was shown during the discussion, the new laws he proposes, however unexceptionable from a scientific standpoint, would introduce undesirable features. As indicated by the title, he proposes to take the whole external volume of a ship in estimating her tonnage and load-line as well as stability. This seems reasonable, but as an illustration of the undesirability of such a law, it may be pointed out that the tendency of the ship designer working for commercial ends, as all designers of mercantile vessels must do, would be to stint engine accommodation to the manifest danger and discomfort of the engineering staff. The subject, is, however, one which we need not pursue.

Mr. Martell's contribution was one full of information and instruction to the designer of light draught vessels. Its value consisted chiefly in the thirteen plates of illustration containing details of construction of a large number of vessels designed for shallow water navigation. The descriptions which accompanied the illustrations were also of great practical information.

M. Sigaudy's paper, on coupling boilers of different systems, was a brief but instructive contribution. The introduction of the water-tube boiler, which may be said now to be complete in the case of small and exceedingly fast war vessels, appears likely to make headway even in craft not of this special description. The water-tube boiler is, however, something new, and the average engineer, engaged in practical work, always shies at novelties. That is but natural, and it is the result of common sense that caution should be observed when risks have to be run. By the system advocated by M. Sigaudy, the risk is reduced to the smallest dimensions. In a tug-boat built by his Company, an ordinary return tube marine boiler is combined with two water-tube boilers. The engineers of the vessel have therefore a steam generator at their disposal, which they thoroughly understand, and which is sufficient to supply steam to drive the boat at moderate speed. Should the water-tube boilers fail, therefore, they would not be left helpless. One advantage of the water-tube boilers is that steam can be raised very quickly, and this is a very desirable feature in a tug which has at times to be used in cases of emergency. The time occupied upon two trials in raising steam was respectively 22 and 23 minutes. The consumption of fuel was 1·78 lbs. per horse-power per hour, which, it need hardly be said, is a very satisfactory result. No trouble has been found, since the tug has been used, to arise from the combination of the two systems of boilers. In the discussion which followed the reading of this paper, Mr. Yarrow stated that a similar system has been adopted by the Dutch Government in some cruisers they are having built. These vessels are naturally of much larger size than the tug-boat described by M. Sigaudy, and their trials will be looked forward to with considerable interest by the naval world.

Dr. Elgar's paper, on the cost of war ships, constituted a new departure in the annals of the Institution. It has generally been considered, if not expressly stated, that financial questions are tabooed by the Institution. In the case of Government vessels, doubtless more latitude should be allowed, but in any event it is a difficult thing to exclude money considerations from discussions on subjects which have a commercial basis. After all, ships are built to earn money, and even the designer of war-ships has to keep the question of cost incessantly before him. It would be useless, for instance, suggesting a new form of marine engine, however perfect from a scientific point of view or economical in its working, if its first cost were to be prohibitive. In the discussion which followed the reading of the paper, views similar to these were expressed by prominent members of the Institution, and it is probable that more latitude will be given for the future in this respect. For our own part, it will be impossible to abstract, in anything like reasonable space, the vast quantities of figures given by the author of the paper. His analysis of the subject was very complete, and it may be stated, briefly, led to the happy conclusion that dockyard-built war vessels are costing less than they did of old, relatively to the work put into them. It may be stated, although Dr. Elgar failed to point the fact out in his paper, that this happy state of affairs is largely due to the good work he himself did when Director of Dockyards.

The last two papers of the meeting were on the subject of the hour, water-tube boilers. M. Normand, the well-known builder of torpedo boats at Havre, and one of the most scientific and best informed marine engineers of the day, gave a very valuable analysis of the points which should be observed in designing a water-tube boiler. Naturally, circulation occupied his chief attention, and it may be said briefly that if sufficient activity of circulation of water and steam in the boiler can be maintained, that boiler is likely to be an efficient steam generator. How to obtain such circulation is a complex and disputed question, and here we find our own great authority on the subject, Mr. Thornycroft, at issue with the author of the paper. Mr. Thornycroft, as is well known, is a strong advocate of above water discharge into the steam drum. M. Normand, on the other hand, upholds "drowned" tubes. The subject is a large one, far too large for discussion in a report of this nature. To us it appears that M. Normand is not warranted in all the assumptions upon which he bases his conclusion, and further it may be said that Mr. Thornycroft has experimental data on his side in maintaining that the circulation of water is more active with above water discharge than with drowned tubes. Whether with the latter the circulation is sufficiently active for all practical purposes is of course another matter, the bearing of which it remains for practical experience to prove. For, like the problem M. Bertin attacked in his paper, it is not solvable by theoretical analysis.

Mr. Mark Robinson, in his paper, described a very promising form of water-tube boiler which has been introduced in France by M. Niclausse, the inventor. Without illustrations it would be utterly impossible to make the design clear; but it may be said that the principle followed is that of the Field tube, in which circulation is promoted by means of a pipe inside and coaxial with the heating tube. Curiously enough, however, the tubes in the Niclausse boiler are horizontal, or approximately horizontal, so that the circulation is maintained in the "header" which is divided by a diaphragm, the difference between the specific gravities of the water, or water and steam, contained on each side of the diaphragm causing the movement of the water. This boiler appears to be one of great promise amongst water-tube boilers in situations where the highest evaporative efficiency is not required. It is, however, in these positions that the ordinary return tube boiler is strongest. Whether it will be supplanted by a water-tube boiler remains to be seen; but should such be the case, the Niclausse boiler has the appearance of being a formidable competitor.

No account of the Paris meeting would be complete without reference being made to the beautiful series of photographs shown by M. Bertin in illustration of the movements of ships in a sea-wave. These photographs were taken by the method devised by M. Marey, to which reference has already been made in these columns. A dozen or more different views are given of a ship during its passage through a wave, and the whole movement can thus be fixed and analysed. The value of such data to the naval architect is, of course, immense. In connection with these photographs, which were shown on the screen, there were also exhibited some very beautiful projections of photographs in colours. These were shown by M. Charles Comte, one of M. Marey's assistants. The subject is one which has been attracting attention of late, and has been referred to elsewhere in these columns.

METEOROLOGICAL PROBLEMS FOR PHYSICAL LABORATORIES.

IN response to several requests from both teachers and students for suggestions as to problems that can be taken up in physical laboratories, Prof. Cleveland Abbe gives the following list of subjects, in the *American Meteorological Journal* for May. The initialled subjects are due to Prof. C. F. Marvin.

SUBJECTS FOR EXPERIMENTAL INVESTIGATION.

(1) The internal sensitiveness of thermometers, or the length of time required to bring the top of the thermometer column to the proper reading when the external surface of bulb and stem is kept at a constant temperature below, or above, some initial temperature.

(2) The influence of the wind on the pressure within a room, or other closed space, containing a barometer.

(3) The influence of the condition of any surface (as to

chemical nature, cleanness, and dust) upon the deposition of dew and the determination of the dew-point.

(4) The behaviour of the wet-bulb thermometer, when covered with water, in an atmosphere of water vapour and of ice vapour.

(5) The influence of radiant heat on wet bulbs covered with ice or water.

(6) The increase of the reading of the wet-bulb thermometer due to any compression that may result from the formation of the ice film on the muslin covering; its dependence on the muslin rather than on the ice.

(7) The determination of the tension of water vapour and ice vapour at and below freezing.

(8) The rate of diffusion of ice vapour as distinguished from aqueous vapour, and also the rates of evaporation from ice and water at the same temperature.

(9) The condensation of vapour in a region free from solid nuclei, and after the temperature has been reduced to, or below, the point of saturation so that the vapour is in a state of unstable equilibrium.

(10) The change that can be produced in the pressure and temperature of a confined volume of *dust free* "dry saturated" steam or other vapour by the introduction of dust particles having various chemical and physical properties. This is the secret of the action of the "cloud engine" of Montgomery J. Storms.

(11) Invention of improved and practical methods of obtaining the moisture contents of the air—especially at low temperatures. C. F. M.

(12) Invention of recording thermometers, barometers, and hygrometers adapted by their accuracy, their extreme lightness, and the quickness with which they respond to atmospheric changes, to be carried up by balloons and by kites in investigations into the condition of the higher atmosphere.—C. F. M.

(13) The development and perfecting of the art of constructing and flying kites with a view of rendering this practically applicable in investigations of the condition of the atmosphere at moderate elevations. C. F. M.

(14) Invention of improved and practical devices for the registration of sunshine and cloudiness, both day and night.—C. F. M.

(15) Invention of devices recording exactly the beginnings and endings, amounts and rates, of precipitation, &c.—C. F. M.

(16) Explanation of the formation of ice-needles in gravelly soil, and determination of the amount of heat and moisture retained at the earth's surface by this formation.

(17) Explanation of the origin of the hollow tubes in the ice-needles and the similar hollow tubes in snow crystals and the analogous holes in hailstones.

(18) The connection between atmospheric conditions and the formation of snow crystals of different shapes and sizes.

(19) The radiating and conducting powers of layers of snow freshly fallen or old and granulated.

(20) The radiation and absorption of heat by dustless, dry air, and also by ordinary atmospheric air containing dust and vapour or ice particles.

(21) Investigation of the formula for computing the velocity and the pressure of the wind from various forms of anemometers, especially the whirling, the pressure, and the suction anemometers.

(22) Invention of the most convenient and cheapest form of nephoscope for determining either direction or velocity, or both these elements of the motion of the clouds.

(23) Investigation of the correction to be made to the record of the ordinary cylindrical rain and snow gauge for the effect of the wind in drifting the rain, and especially the snow.

(24) Study of the temperature of the soil at different depths from the surface-layer down to three feet and under different conditions, as to moisture-content, sunshine, and wind.

(25) Invention of better methods of determining at any moment the temperature and moisture at any depth in the soil.

(26) Determination of the quantity of water evaporated from natural surfaces, especially ocean water, ice or snow, fresh water, and forests or cultivated fields, and its relation to humidity, temperature, and wind.

(27) Improvements in the actinometer and a series of determinations of the amounts of heat received at any point, both from the sun directly and from the clouds and the atmosphere by reflection or radiation.

(28) Observations of the polarisation and the intensity of blue sky light and comparison with optical theories.

(29) Instrumental methods for recording some of the various chemical effects directly produced by solar radiation, and which are of special importance in the growth of plants, the decomposition of the soil, and the purification of water.

(30) A series of determinations or, still better, a continuous record of the simultaneous differences of electric potential between the earth's surface, and several points in the free atmosphere, one hundred feet apart, vertically, meridionally, and prime-vertically.

(31) A similar series for several points beneath the earth's surface as to their electro-magnetic condition, and a correlation of the distribution of electric conditions with the electric currents in the air and the earth.

(32) A study of the scintillation of the stars and its relation to atmospheric conditions.

(33) A study of the apparent acoustic opacity of the atmosphere at certain places and times.

(34) An explanation of the sounds attending large aerolites, and an explanation as to what may be learned therefrom regarding the upper atmosphere and in regard to the improvement of fog signals.

(35) A study of the formation of halos, parhelia, and corona, by the action of snow crystals and water-drops on sunlight.

(36) Investigation of the first step in the process of convection, as it occurs in the free atmosphere by which small currents of warm air, rising as slender rolls and whirls, mix with the cooler air, and are broken up within a few feet of the earth's surface; a determination of the limit at which such convection becomes inappreciable.

(37) A study of the larger convection currents, their relation to the horizontal motion, the extent to which they retard and accelerate the motions or increase and decrease the pressures in the upper and lower strata.

THE SENSES OF INSECTS.[1]

OF the five ordinary senses recognised in ourselves and most higher animals, insects have, beyond all doubt, the sense of sight, and there can be as little question that they possess the senses of touch, taste, smell, and hearing. Yet, save perhaps that of touch, none of these senses, as possessed by insects, can be strictly compared with our own, while there is the best of evidence that insects possess other senses which we do not, and that they have sense organs with which we have none to compare. He who tries to comprehend the mechanism of our own senses—the manner in which the subtler sensations are conveyed to the brain—will realise how little we know thereof after all that has been written. It is not to be wondered at, therefore, that authors should differ as to the nature of many of the sense organs of insects, or that there should be little or no absolute knowledge of the manner in which the senses act upon them. The solution of psychical problems may never, indeed, be obtained, so infinitely minute are the ultimate atoms of matter; and those who have given most attention to the subject must echo the sentiment of Lubbock, that the principal impression which the more recent works on the intelligence and senses of animals leave on the mind is that we know very little, indeed, on the subject. We can but empirically observe and experiment and draw conclusions from well attested results.

Sight. Taking first the sense of sight, much has been written as to the picture which the compound eye of insects produces upon the brain or upon the nerve centres. Most insects which undergo complete metamorphoses possess in their adolescent states simple eyes or ocelli, and sometimes groups of them of varying size and in varying situations. It is difficult, if not impossible, to demonstrate experimentally their efficiency as organs of sight; the probabilities are that they give but the faintest impressions, but otherwise act as do our own. The fact that they are possessed only by larvæ which are exposed more or less fully to the light, while those larvæ which are endophytous, or otherwise hidden from light, generally lack them, is in itself proof that they perform the ordinary functions of sight, however low in degree. In the imago state the great majority of insects have their simple eyes in addition to the compound eyes. In many cases, however, the former are more or less covered with vestiture, which is another evidence that their function is of a low

[1] From an address on "Social Insects," delivered by Prof. C. V. Riley, as President of the Biological Society of Washington. (Reprinted (slightly condensed) from *Insect Life*, vol. vii. No. 1.)

order, and lends weight to the view that they are useful chiefly for near vision and in dark places. The compound eyes are prominent and adjustable in proportion as they are of service to the species, as

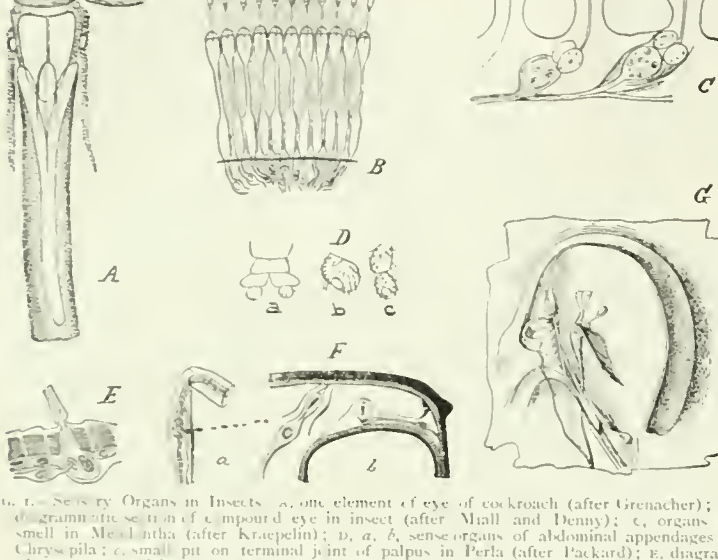

Fig. 1.—Sensory Organs in Insects: A, one element of eye of cockroach (after Grenacher); B, diagrammatic section of compound eye in insect (after Miall and Denny); C, organs of smell in Melolontha (after Kraepelin); D, *a*, *b*, sense-organs of abdominal appendages of Chrysopila; *c*, small pit on terminal joint of palpus in Perla (after Packard); E, diagram of sensory ear of insect (after Miall and Denny); F, auditory apparatus of Meconema; *a*, fore tibia of this locust; *b*, diagrammatic section through same (after Graber); G, auditory apparatus of Caloptenus, seen from inner side, showing tympanum, auditory nerve, terminal ganglion, stigma, and opening and closing muscle of same, as well as muscle of tympanum membrane (after Graber). All very greatly enlarged.

witness those of the common house-fly and of the Libellulidæ or dragon-flies. It is obvious from the structure of these compound eyes that impressions through them must be very different from those received through our own, and, in point of fact, the experimental researches of Hickson, Plateau, Tocke and Lemmermann, Pankrath, Exner, and Viallanes have practically established the fact that while insects are shortsighted and perceive stationary objects imperfectly, yet their compound eyes are better fitted than the vertebrate eye for apprehending objects set in relief or in motion, and are likewise keenly sensitive to colour.

So far as experiments have gone, they show that insects have a keen colour sense, though here again their sensations of colour are different from those produced upon us. Thus, as Lubbock has shown, ants are very sensitive to the ultra-violet rays of the spectrum, which we cannot perceive, though he was led to conclude that to the ant the general aspect of nature is presented in an aspect very different from that in which it appears to us. In reference to bees, the experiments of the same author prove clearly that they have this sense of colour highly developed, as indeed might be expected when we consider the part they have played in the development of flowers. While these experiments seem to show that blue is the bee's favourite colour, this does not accord with Albert Müller's experience in nature, nor with the general experience of apiarians, who, if asked, would very generally agree that bees show a preference for white flowers.

Touch.—The sense of touch is supposed to reside chiefly in the antennæ or feelers, though it requires but the simplest observation to show that with soft-bodied insects the sense resides in any portion of the body, very much as it does in other animals.

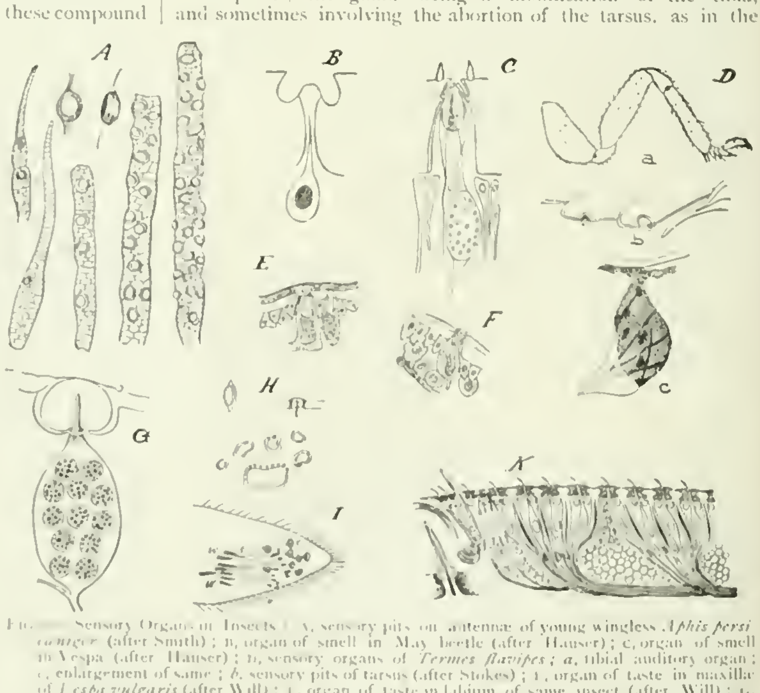

Fig. 2.—Sensory Organs in Insects: A, sensory pits on antennæ of young wingless *Aphis persicæniger* (after Smith); B, organ of smell in May beetle (after Hauser); C, organ of smell in Vespa (after Hauser); D, sensory organs of *Termes flavipes*; *a*, tibial auditory organ; *c*, enlargement of same; *b*, sensory pits of tarsus (after Stokes); E, organ of taste in maxillæ of *Vespa vulgaris* (after Will); F, organ of taste in labium of same insect (after Will); G, organ of smell in Caloptenus (after Hauser); H, sensory pilose depressions on tibia of Termes (after Stokes); I, terminal portion of antennæ of *Myrmica ruginodis*, *c*, cork-shaped organs; *s*, outer sac; *t*, tube; *w*, posterior chamber (after Lubbock); K, longitudinal section through portion of flagellum of antennæ of worker bee, showing sensory hairs and supposed olfactory organs (after Cheshire). All very greatly enlarged.

In short, this is the one sense which, in its manifestations, may be conceded to resemble our own. Yet it is evidently more specialised in the maxillary and labial palpi and the tongue than in the antennæ in most insects.

Taste.—Very little can be positively proved as to the sense of taste in insects. Its existence may be confidently predicated from the acute discrimination which most monophagous species exercise in the choice of their food, and its location may be assumed to be the mouth or some of the special trophial organs which have no counterpart among vertebrates. Indeed, certain pits in the epipharynx of many mandibulate insects and in the ligula and the maxillæ of bees and wasps are conceded by the authorities to be gustatory.

Smell.—That insects possess the power of smell is a matter of common observation, and has been experimentally proved. The many experiments of Lubbock upon ants left no doubt in his mind that the sense of smell is highly developed in them. Indeed, it is the acuteness of the sense of smell which attracts many insects so unerringly to given objects, and which has led many persons to believe them sharp-sighted. Moreover, the innumerable glands and special organs for secreting odours furnish the strongest indirect proof of the same fact. Some of these, of which the osmaterium in Papilionid larvæ and the eversible glands in Parorgyia are conspicuous examples, are intended for protection against inimical insects or other animals; while others, possessed by one only of the sexes, are obviously intended to please or attract. A notable development of this kind is seen in the large gland on the hind legs of the males of some species of Hepialus, the gland being a modification of the tibia, and sometimes involving the abortion of the tarsus, as in the European *H. hectus* (L.) and our own *H. behrensi* (Stretch.) The possession of odoriferous glands, in other words, implies the pos-

session of olfactory organs. Yet there is among insects no one specialised olfactory organ as among vertebrates; for while there is conclusive proof that this sense rests in the antennæ with many insects, especially among Lepidoptera, there is good evidence that in some Hymenoptera it is localised in an ampulla at the base of the tongue, while Graber gives reasons for believing that in certain Orthoptera (Blattidæ) it is located in the anal cerci and the palpi.

Hearing.—In regard to the sense of hearing, the most casual experimentation will show (and general experience confirms it) that most insects, while keenly alive to the slightest movements or vibrations, are for the most part deaf to the sounds which affect us. That they have a sense of sound is equally certain, but its range is very different from ours. A sensitive flame, arranged for Lubbock by the late Prof. Tyndall, gave no response from ants, and a sensitive microphone, arranged for him by Prof. Bell, gave record of no other sound than the patter of feet in walking. But the most sensitive tests we can experimentally apply may be, and doubtless are, too gross to adjust themselves to the finer sensibilities of such minute, active, and nervous creatures. There can be no question that insects not only produce sounds, but receive the impression of sounds entirely beyond our own range of perception, or, as Lubbock puts it, that "we can no more form an idea of than we should have been able to conceive red or green if the human race had been blind. The human ear is sensitive to vibrations reaching at the outside to 38,000 in a second. The sensation of red is produced when 470 millions of millions of vibrations enter the eye in a similar time; but between these two numbers vibrations produce on us only the sensation of heat. We have no especial organ of sense adapted to them." It is quite certain that ants do make sounds, and the sound-producing organs on some of the abdominal joints have been carefully described. The fact that so many insects have the power of producing sounds that are even audible to us, is the best evidence that they possess auditory organs. These are, however, never vocal, but are situated upon various parts of the body, or upon different members thereof.

Special Sense and Sense Organs.—While from what has preceded it is somewhat difficult to compare the more obvious senses possessed by insects with our own, except perhaps in the sense of touch, it is, I repeat, just as obvious to the careful student of insect life that they possess special senses which it is difficult for us to comprehend. The sense of direction, for instance, is very marked in the social Hymenoptera which we have been considering, and in this respect insects remind us of many of the lower vertebrates which have this sense much more strongly developed than we have. Indeed, they manifest more especially what has been referred to in man as a sixth sense, viz. a certain intuition which is essentially psychical, and which undoubtedly serves and acts to the advantage of the species as fully, perhaps, as any of the other senses. Lubbock demonstrated that an ant will recognise one of its own colony from among the individuals of another colony of the same species; and when we consider that the members of a colony number at times, not thousands, but hundreds of thousands, this remarkable power will be fully appreciated.

The neuter Termites are blind, and can have no sense of light in their internal or subterranean burrowings; yet they will undermine buildings, and pulverise various parts of elaborate furniture without once gnawing through to the surface; and those species which use clay, will fill up their burrowings to strengthen the supports of structures which might otherwise fall and injure the insects or betray their work. The bat in a lighted room, though blinded as to sight, will fly in all directions with such swiftness and infallible certainty of avoiding concussion or contact, that its feeling at a distance is practically incomprehensible to us.

Telepathy.—But however difficult it may be to define this intuitive sense which, while apparently combining some of the other senses, has many attributes peculiar to itself, and however difficult it may be for us to analyse the remarkable sense of direction, there can be no doubt that many insects possess the power of communicating at a distance, of which we can form some conception by what is known as telepathy in man. This power would seem to depend neither upon scent nor upon hearing in the ordinary understanding of these senses, but rather on certain subtle vibrations as difficult for us to comprehend as is the exact nature of electricity. The fact that men can telegraphically transmit sound almost instantaneously around the globe, and that his very speech may be telephonically transmitted, as quickly as uttered, for thousands of miles, may suggest something of this subtle power, even though it furnish no explanation thereof.

The power of sembling amongst certain moths, for instance, especially those of the family Bombycidæ, is well known to entomologists, and many remarkable instances are recorded. I am tempted to put on record for the first time an individual experience which very well illustrates this power, as on a number of occasions when I have narrated it most persons not familiar with the general facts have deemed it remarkable. In 1863 I obtained from the then Commissioner of Agriculture, Colonel Capron, eggs of *Samia cynthia*, the Ailanthus silkworm of Japan, which had been recently introduced by him. I was living in Chicago at the time, and in my garden there grew two Ailanthus trees, which were the cause of my sending for the aforesaid eggs. I had every reason to believe that there were no other eggs of this species received in any part of the country within hundreds of miles around. It seemed a good opportunity to test the power of this sembling, and after rearing a number of larvæ I carefully watched for the appearance of the first moths from the cocoons. I kept the first moths separate, and confining a virgin female in an improvised wicker cage out of doors on one of the Ailanthus trees. On the same evening I took a male to another part of the city, and let him loose, having previously tied a silk thread around the base of the abdomen to insure identification. The distance between the captive female and the released male was at least a mile and a half, and yet the next morning these two individuals were together.

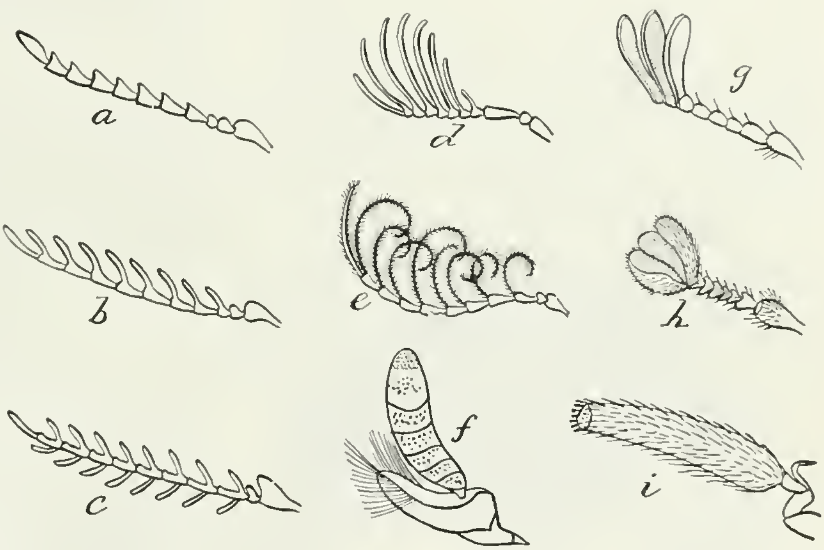

FIG. 3.—Some Antennæ of Coleoptera: *a*, Ludius; *b*, Corymbites; *c*, Prinocyphon; *d*, Acneus; *e*, Dendroides; *f*, Dineutes; *g*, Lachnosterna; *h*, Bolbocerus; *i*, Adranes (after Le Conte and Horn). All greatly enlarged.

Now, in the moths of this family the male antennæ are elaborately pectinate, the pectinations broad and each branch minutely hairy (see Fig. 5, *a*.) These feelers vibrate incessantly, while in the female, in which the feelers are less complex, there is a similar movement connected with an intense vibration of the whole body and of the wings. There is, therefore, every reason to believe that the sense is in some way a vibratory sense, as, indeed, at base is true of all senses, and no one can study the wonderfully diversified structure of the antennæ in insects,

especially in males, as very well exemplified in some of the commoner gnats (see Fig. 5, *d*, *e*), without feeling that they have been developed in obedience to, and as a result of, some such subtle and intuitive power as this of telepathy. Every minute ramification of the wonderfully delicate feelers of the male mosquito, in all probability, pulsates in response to the piping sounds which the female is known to produce, and doubtless through considerable distance.

There is every justification for believing that all the subtle cosmic forces involved in the generation and development of the

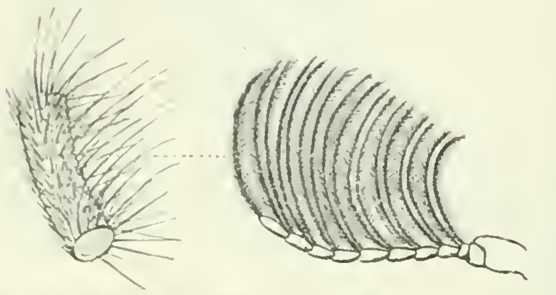

Fig. 4.—Antenna of male Phengodes with portion of ray.—Greatly enlarged (original).

highest are equally involved in the production and building up of the lowest of organisms, and that the complexing and compounding and specialisation of parts have gone on in every possible and conceivable direction, according to the species. The highly developed and delicate antennæ in the male Chironomus, for instance, may be likened to an external brain, its ramifying fibres corresponding to the highly complicated pro-

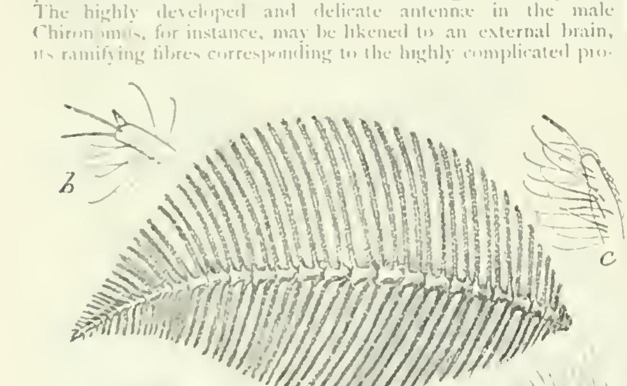

Fig. 5.—[illegible] Antennæ of [illegible] *a*, Telephorus [illegible] male [illegible]; *b*, [illegible] still more enlarged; *d*, Chironomus × 6; *e*, [illegible] still more enlarged (original).

cesses that ramify from the nerve cells in the internal brains of higher animals, and responding in a somewhat similar way to external impressions. While having no sort of sympathy with the foolish notions that the spiritualists proclaim, to edify or terrify the gullible and unscientific, I am just as much out of sympathy with that class of materialists who refuse to recognise that there may be and are subtle psychical phenomena beyond the reach of present experimental methods. The one class too readily assumes supernatural power to explain abnormal phenomena; the other denies the abnormal, because it, likewise, is past our limited understanding.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The Harkness Scholarship in Geology has been awarded to Arthur William Rogers, of Christ's College.

Mr. J. S. Gardiner, of Caius College, has been chosen to occupy the University's table at the Naples Zoological Station for six months from October 1.

The Newall Observer reports that the fine spectroscope designed for use with the Newall Telescope is now ready, and that the preliminary trials of it have been satisfactory. The mounting has been made by the Cambridge Scientific Instrument Company, and the optical parts by Mr. Brashear, of Alleghany.

Mr. F. Darwin, Mr. W. G. P. Ellis, Prof. Liveing, Mr. T. B. Wood, Prof. M. Foster, Mr. A. Eichholz, Mr. A. E. Shipley, Mr. C. Warburton, Prof. Hughes, Mr. P. Lake, Mr. O. P. Fisher, Mr. J. Owen, Mr. R. Menzies, and Mr. C. B. Fisher, have been appointed Examiners in the Science and Art of Agriculture for the University Diploma. The examination will be held in July.

Sir David L. Salomons, Bart., has founded, in connection with Caius College, a Scholarship in Engineering. The first award will be made in October. The value of the Scholarship is £40 a year for three years. The Salomons Scholar must become a candidate for the Mechanical Sciences Tripos. Applications for further information should be made to the Tutors of Caius College.

The Conference on Technical Education held at the Society of Arts last Thursday, resulted in the adoption of the following resolution:—"That in the opinion of this meeting it is desirable that provision should be made for examination and inspection in the subjects of instruction undertaken by technical instruction committees but not at present included in the schemes of the Science and Art Department, the City and Guilds of London Institute, and the Society of Arts, and that with the object of giving effect to the same this conference recommends that a representative committee be appointed to draw up a report and prepare recommendations on the whole subject."

SCIENTIFIC SERIALS.

American Journal of Science, June.—The preparation of perchloric acid and its application to the determination of potassium, by D. Albert Kreider. The difficulty attending the removal of the potassium in the ordinary preparation of this acid from potassium chlorate may be overcome by using the sodium salt instead. The insolubility of chloride of sodium in strong hydrochloric acid, with the aid of the acid-proof Gooch crucible, affords a means for the liberation of the perchloric acid and the removal of the greater part of the sodium in one operation. Sodium chlorate is heated until it gives off oxygen. When all the possible oxygen has been given off, and only the chloride and the perchlorate remain, the residue is treated with strong hydrochloric acid and filtered. The perchloric acid is thus liberated, and the sodium precipitated as chloride. The liquid is decanted, and undergoes the same operation again. The solution, containing hydrochloric and perchloric acids and a small amount of sodium chloride, is evaporated till the former acid is driven off and the heavy white fumes of the perchloric acid appear. It is then ready for potassium determinations, with which the small residue of sodium does not interfere. The filtering is done by means of a Gooch crucible, and the operation requires less time and attention than the old process, and is much less dangerous.—Mode of growth and development of the graptolitic genus *Diplograptus*, by R. Ruedemann. By the possession of a pneumatocyst and the arrangement of the reproductive organs at the bases of the stipes, the colonial stocks of *Diplograptus* have a general similarity to those of certain *Siphonophoræ*, while the chitinous structure of the hydrothecæ and gonangia can only be referred to the Sertularians. It thus becomes evident that the genus *Diplograptus*, like so many palæozoic fossils, has the combined properties of different groups, thus giving valuable hints in regard to the common ancestors of those groups.—On the elevation along the Rocky Mountain range in British America since the close of the Cretaceous period, by Dr. G. M. Dawson. In the mountains, the cretaceous rocks have been involved in all the flexure, faulting, and overthrust suffered by the Palæozoic; and both in the mountains and foothills these rocks are found at all angles up to vertical, and even overturned.

It is thus difficult to know the amount of elevation of these rocks, but about latitude 50° the base of the cretaceous must in several places have considerably exceeded 10,000 feet in altitude.

Symons's Monthly Meteorological Magazine, June. The principal article deals with rainfall in China, with remarks by the editor, based on observations made from 1886-92, and published in various places by Dr. Doberck, of Hong Kong. The mean annual rainfall is small in the north, and increases greatly towards the south. In the Gulf of Pe-chi-li the fall is 20 inches, but reaches double that amount in the Delta of the Yang-Tse-Kiang, 58 inches at Hankow, and 68 inches at Ningpo. In Formosa it ranges from 60 to 90 inches, but at Keelung, in the north-east, it reaches 148 inches. The seasonal rainfall is shown in tables divided into six districts. Notwithstanding the proximity of most of the stations to the sea, the distribution is, generally speaking, of that type which prevails over the greater part of Asia.

SOCIETIES AND ACADEMIES.

London.

Royal Society, January 24.—"Micro-Metallography of Iron." Part I. By Thomas Andrews, F.R.S.

In the course of a research with high microscopical powers (including 300, 500, 800, 1200, and upwards to 2000 diameters) on the micro-crystalline structure of large masses of wrought iron, the author observed the following novel metallurgical facts:—

When large masses, several tons in weight, of practically pure wrought iron were allowed to slowly cool from a white heat, a secondary or subcrystallisation of the metallic iron occurred. The normal primary crystals of the iron, or those which have hitherto been regarded as constituting the ultimate structure of the metal, were found to enclose a subcrystalline formation consisting of very minute, and much smaller, crystals of pure iron also belonging to the regular order of crystallisation. These crystals sometimes manifested the hexagonal form, the predominant angle being about 120°, and often they assumed the form of simple cubes. The secondary crystals were contained within the area of the larger primary crystals.

Typical illustrations of this duplex crystallisation found in two large iron forgings are given in Figs. 1 and 2, and the relative dimensions of a number of individual crystals are given in the paper.

The results of twenty measurements of the primary crystals and twenty measurements of the secondary crystals taken on each forging are given on these tables.

The markings of the intercrystalline spaces or junctions of the secondary crystals were very clearly defined, but they were exceedingly minute. The general form, contour, and relative size of the primary and secondary crystals, as seen in section, will be noticed on reference to the accurate tracings, Figs. 1 and 2. The linear dimensions of the primary crystals would average about 0·01 inch, the linear dimensions of the secondary crystals averaging about 0·001 inch.

Judging roughly from the indications of the average micro-measurements, there would appear to be approximately 1,000,000,000 of the secondary crystals in a cubic inch of the metallic iron.

In the case of both the primary and secondary crystals the predominant well-defined angles of the facets of the crystals hovered more or less about the angle of 120°. The majority of the angle readings, made with the goniometer attached to the microscope, indicating generally a hexagonal structure on form of crystallisation. There were, however, also perfect cubical crystals observed.

The observations were made with a Ross first-class microscope. The micro-measurements afford an indication of the comparative size of the primary and secondary crystals. These measurements were carefully taken by a Jackson micrometer, and in some cases by a Ramsden screw micrometer, both accurately calibrated with a standard stage micrometer. The wrought iron forgings on which the observations were made were constituted of practically pure hammered wrought iron, the dimensions of the mass being about 10 feet long and about 12 inches square. The great length of time required for such large masses of iron to cool from a white heat appeared to facilitate the production of the crystals of the secondary formation.

The *rationale* of this duplex crystallisation has apparently been as follows:—The mass of metallic iron on cooling having reached the crystallising point at about 740° C., the periphery or skeletons of the larger or primary crystals were then formed. As the period of cooling was, however, very slow, the semi-fluid or viscous metal in the interior of these primary crystals was, on finally consolidating, apparently further broken up or subdivided

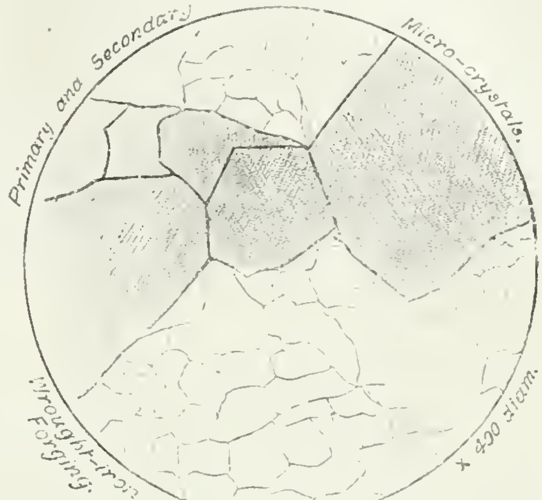

Fig. 1.

into a considerable number of smaller crystals, enclosed within the boundary or periphery of the primary crystals.

In the course of further experiments on the cooling of large masses of wrought iron, the author has also found, by the use of high power objectives, that the secondary crystals sometimes enclosed a still more minute form of crystals of pure iron, of the cubical form, which may hence be regarded as constituting a tertiary system of crystallisation in pure metallic iron. These

Fig. 2.

experiments therefore indicate that large masses of heated wrought iron, on cooling from above the temperature of the crystallisation of metallic iron, viz. 740° C., are capable of crystallising in three distinct modifications which may tentatively be called the primary, secondary, and tertiary system of crystallisation in iron, these various crystalline modifications being all, however, connected with the regular system of crystallisation.

The crystals of this secondary formation are not often distinctly discernible in smaller masses of metallic iron, such as rolled rods, plates, or sheets, as these in the course of manufacture rapidly cool, and are frequently manipulated during the finishing processes at temperatures below the crystallising point of wrought iron (740° C.).

The microscopical examinations were made on carefully prepared and polished samples, etched in nitric acid (1 part HNO_3, sp. gr. 1·20, and 49 parts water), and by the use of high microscopical powers ($\frac{1}{8}$-inch to $\frac{1}{16}$-inch, and other ojectives). The drawings were accurately made with the camera lucida. In each observation the etching was prolonged, under constant observation with lenses, a suitable time to develop the accurate structure of the metal.

June 13.—"On the New Gas obtained from Uraninite." Fourth Note. By J. Norman Lockyer, C.B., F.R.S.

Continued experiments on the gases obtained by heating the minerals broggerite and euxenite *in vacuo* have revealed the presence in the spectrum of an important line in the infra-red. By comparisons with the solar spectrum in the first order grating spectrum, the wave-length of the line has been approximately

(2) Contrariwise, when we are dealing with a known compound gas: at the lowest tension we may get the complete spectrum of the compound without any trace of its constituents, and we may then, by increasing the tension, gradually bring in the lines of the constituents until, when complete dissociation is finally reached, the spectrum of the compound itself disappears.

Working on these lines, the spectrum of the spark at atmospheric pressure, passing through the gas, or gases, distilled from bröggerite, has been studied with reference to the special lines C (hydrogen), D_3, 667, and 447.

The first result is that all the lines do not vary equally, as they should do if we were dealing with a simple gas.

The second result is that at the lowest tension 667 is relatively more brilliant than the other lines; on increasing the tension, C and D_3 considerably increase their brilliancy, 667 relatively and absolutely becoming more feeble; while 447, seen easily as a narrow line at low tension, is almost broadened out into invisibility as the tension is increased in some of the tubes, or is greatly brightened as well as broadened in others (Fig. 1).

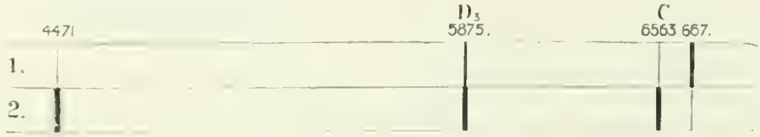

Fig. 1.—Diagram showing changes in intensities of lines brought about by varying the tension of the spark. (1) Without air-break. (2) With air-break.

determined as 7065. There can be little doubt, from the observations which have been made, that this new line is coincident with a chromospheric line which occurs in Young's list, having a frequency of 100, and of which the wave-length on Rowland's scale is stated to be 7065·5.

It follows therefore that, besides the hydrogen lines, all three chromospheric lines in Young's list which have a frequency of 100 have now been recorded in the spectra of the new gas or gases obtained from minerals by the distillation method.

These are as follows:—

7065·5
5875·98
4471·8

The wave-lengths of the lines are in Rowland's scale, as given in Scheiner's "Astronomical Spectroscopy."[1] In a partial

The above observations were made with a battery of five Grove cells; the reduction of cells from 5 to 2 made no difference in the phenomena except in reducing their brilliancy.

Reasoning from the above observations, it seems evident that the effect of the higher tension is to break up a compound, or compounds, of which C, D_3, and 447 represent constituent elements; while, at the same time, it would appear that 667 represents a line of some compound which is simultaneously dissociated.

The unequal behaviour of the lines has been further noted in another experiment, in which the products of distillation of bröggerite were observed in a vacuum tube and photographed at various stages. After the first heating, D_3 and 4471 were seen bright, before any lines other than those of carbon and hydrogen made their appearance. With continued heating, 667, 5016, and 492 also appeared, although there was no notable increase of

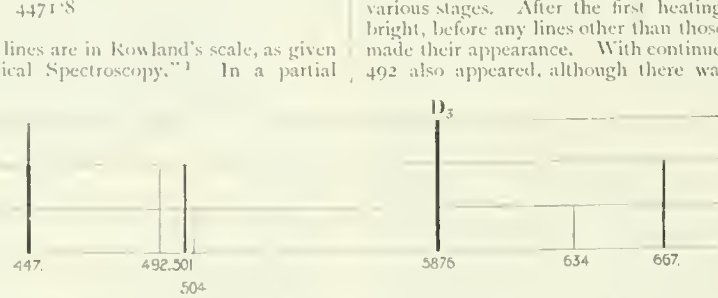

Fig. 2.—Diagram showing order in which lines appear in spectrum of vacuum tube when bröggerite is heated.

revision of his chromospheric list, Prof. Young gives the *corona* line 5316·79 as also having a frequency of 100 in the chromosphere, but, up to the present, this line has not been among those obtained in the laboratory.

"On the New Gas obtained from Uraninite." Fifth Note. By J. Norman Lockyer, C.B., F.R.S.

In a former communication I pointed out the spectroscopic evidence, furnished by the isolation of lines in certain minerals, which indicates that the complete spectrum obtained when broggerite is submitted to the distillation method is produced by a mixture of gases.

In order to test this view, I have recently made some observations, based on the following considerations:

(1) In a simple gas like hydrogen, when the tension of the electric current given by an induction coil is increased, by inserting first a jar, and then an air-break into the circuit, the effect is to increase the brilliancy and breadth of all the lines, the brilliancy and breadth being greatest when the longest air-break is used.

[1] Fr[illegible] translation, p. 1[illegible]4.

brightness in the yellow line; still further heating introduced additional lines 5048 and 6347.

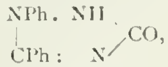
These changes are represented graphically in the following diagram (Fig. 2).

It was recorded further that the yellow line was at times dimmed, while the other lines were brightened.

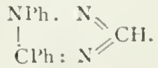
"On the Origin of the Triradiate Spicules of *Leucosolenia*." By E. A. Minchin.

Chemical Society, June 6.—Mr. A. Vernon Harcourt, President, in the chair. The following papers were read: The molecular refractions of dissolved salts and acids, by J. H. Gladstone and W. Hibbert. The authors show that in many cases when a pure substance dissolves in water, an alteration of its specific refractive energy occurs.—A comparison of some properties of acetic acid and its chloro- and bromo-derivatives, by S. U. Pickering. A number of thermal and other physical properties of acetic acid, and its monochloro- and monobromoderivatives have been quantitatively examined and compared; four distinct crystalline modifications of monochloracetic acid

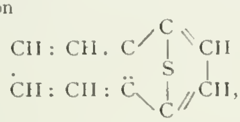
have been prepared.—$\beta\beta$-Dinaphthyl and its quinones, by F. D. Chattaway. Two quinones are obtained by oxidising $\beta\beta$-dinaphthyl under different conditions; from their chemical behaviour these seem to be β-naphthyl naphthoquinone, $C_{10}H_5.O.C_{10}H_7.O$ (1 : 2 : 4) and $\beta\beta$-di-α-naphthoquinone, $C_{10}H_5O_2.C_{10}H_5O_2$ (1 : 2 : 4 : 1 : 2 : 4).—Action of benzaldehyde on phenylsemicarbazide, by G. Young. The interaction of benzaldehyde and phenylsemicarbazide yields a diphenyloxytriazole



which on reduction gives diphenyltriazole



—Note on the latent heat of fusion, by N. F. Deerr. Acid compounds of some natural yellow colouring matters, part 1, by A. G. Perkin and L. Pate. The yellow colouring matters, quercitin, rhamnazin, rhamnetin, luteolin, fisetin and morin form orange or scarlet crystalline compounds with some of the mineral acids; catechin and maceurin do not yield such compounds.—Action of sulphur on α-nitronaphthalene, by A. Herzfelder. On heating a mixture of sulphur and α-nitronaphthalene an amorphous substance is obtained, which probably has the constitution



and to which the name $\alpha\alpha^1$-thionaphthalene is given.

Mathematical Society, June 13.—Major MacMahon, R.A., F.R.S., President, in the chair.—Mr. G. H. Bryan, F.R.S., communicated a note on an extension of Boltzmann's minimum theorem, by Mr. S. H. Burbury, F.R.S.—Dr. J. Larmor, F.R.S., gave a brief sketch of a paper by Mr. J. Brill, entitled "On the form of the energy integral in the variable motion of a viscous incompressible fluid for the case in which the motion is two dimensional, and the case in which the motion is symmetrical about an axis."—A paper by Dr. Routh, F.R.S., on an expansion of the potential function $1/R^{\kappa-1}$ in Legendre's functions, was taken as read.—Mr. Macaulay read a paper entitled "Groups of points on curves treated by the method of residuation." The President stated that Prof. A. M. Nash, of the Presidency College, Calcutta, had died on the voyage home, for a two years' furlough, after twenty years' residence in India.

Zoological Society, June 18.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—Mr. J. Graham Kerr read a paper on some points in the anatomy of *Nautilus pompilius*. The author advocated the abandonment of the view that the arms in Cephalopods are pedal, and the resumption of what appeared the inherently more probable view, that they are processes of the head-region. In conclusion, the author drew attention to certain indications which appeared to point to the Amphineura, and especially to the Chitons, as being of all living Mollusca those which most nearly approximate to the ancestral form of the time when the Cephalopods diverged from the main Molluscan stem.—A communication was read from Mr. F. E. Beddard, F.R.S., and Mr. A. C. Haddon, containing an account of a collection of Nudibranchiate Mollusca recently made by the latter in Torres Straits.—Mr. Boulenger read a paper on a large collection of fishes made by Dr. C. Ternitz in the Rio Paraguay.—A communication was read from the Babu Ram Bramha Sányál, giving an account of the moulting of some Birds of Paradise in the Zoological Gardens, Calcutta.—A communication was read from Mr. O. Thomas and Colonel J. W. Yerbury, giving a description of a collection of mammals made at Aden by Colonel Yerbury in the winter of this year. It was shown that thirty-six species of mammals were now known to occur in the Aden district.—A communication was read from Mr. Edwyn C. Reed, containing a list of the Hemiptera-Heteroptera of Chili.—Mr. H. H. Druce read a paper on Bornean butterflies of the family Lycænidæ, in which he had catalogued all the species already recorded from that island, and gave descriptions of a considerable number of new species, principally from Mount Kina-Balu. Mr. Druce stated that the number of butterflies of this family previously recorded from Borneo was about 75, and that his paper contained references to about 220.—A communication was read from Dr. A. G. Butler, containing an account of a small collection of butterflies sent by Mr. R. Crawshay from the country west of Lake Nyasa. Five species were described as new to science.—Mr. J. Anderson, F.R.S., read a paper describing a collection of reptiles and batrachians made by Colonel Yerbury at Aden and its neighbourhood during the past winter.—Mr. Boulenger, F.R.S., gave an account of the reptiles and batrachians collected by Dr. A. Donaldson Smith during his recent expedition in Western Somaliland and the Galla country.

Royal Meteorological Society, June 19.—Mr. R. Inwards, President, in the chair.—Mr. R. H. Curtis read a paper on the hourly variation of sunshine at seven stations in the British Isles, which was based upon the records for the ten years 1881-90. Falmouth is decidedly the most sunny station of the seven, having a daily average amount of sunshine of $4\frac{1}{2}$ hours. This amount is half an hour more than that recorded at Valencia, and three-quarters of an hour more than at Kew. Of the other four stations, Aberdeen, the most northern but at the same time a coast station, with 3·64 hours, has more than either Stonyhurst or Armagh, both inland stations; whilst Glasgow, with only 3 hours, or about a quarter of its possible amount, has the smallest record of the seven, a result to some extent due to the nearness of the observatory to the large manufacturing works with which the city of Glasgow abounds. At Valencia, Kew, Stonyhurst, and Armagh, the maximum duration is reached in May, the daily mean amount varying in the order named from $6\frac{3}{4}$ to 6 hours. At Falmouth and at the Scotch stations the increase goes on to June, when the mean duration at Falmouth reaches $7\frac{1}{2}$ hours, at Aberdeen $6\frac{1}{4}$ hours, and at Glasgow 5·6 hours. January and December are the most sunless months of the year. The most prominent feature brought out at all the stations is the rapid increase in the mean hourly amount of sunshine recorded during the first few hours following sunrise, and the even more rapid falling off again just before sunset.—Mr. H. Harries read a paper on the frequency, size, and distribution of hail at sea. The author has examined a large number of ships' logs in the Meteorological Office, and finds that hail has been observed in all latitudes as far as ships go north and south of the equator, and that seamen meet with it over wide belts on the polar side of the 35th parallel.

Royal Irish Academy, June 10.—Dr. J. K. Ingram, President, in the chair.—A paper on a basaltic hill of Tertiary age in county Galway, by A. MacHenry and Prof. W. J. Sollas, F.R.S., was read (communicated by permission of the Director-General of the Geological Survey). The extensive occurrence of basaltic dykes running with a general north-west to south-east direction through the whole northern third of Ireland has been described by Sir Archibald Geikie, who, in a bold but true generalisation, has referred them to the Tertiary period. The authors bring forward evidence of a still more southern and western extension of igneous activity in Ireland during this period, basaltic rocks similar to those of Antrim being shown to occur at Bunowen, seven miles south-west of Clifden, and thus about five or six miles north of the latitude of Dublin. They form a hill rising to a height of 200 feet above the surrounding plain, which is composed of gneissose rocks, through which the basalt has been extruded. The hill trends from north to south, and is 450 yards in length. It consists of olivine bearing dolerite, and vasicular basalt containing unaltered glass, and a substance which has been described [1] as a mineral under the name of "hullite." This substance is shown not only to occur in the vesicles of the basalt as volcanic glass does in the "amygdaloids" of the Tynemouth dyke described by Teall, but also to contribute to the ground mass, where it presents all the characters of an interstitial glass. Its most remarkable character is its extremely low specific gravity (1·76), which is small even for a hydrous volcanic glass, such as this so-called mineral must be admitted to be.

PARIS.

Academy of Sciences, June 17.—M. Cornu in the chair.—The President announced to the Academy the decease of M. Verneuil, member of the Medicine and Surgery Section.—A note on the law of absorption of bands of the oxygen spectrum, by M. J. Janssen.—On the necessarily harmonic form of displacements in ocean rollers, even when the

[1] "On Hullite," by E. T. Hardman and E. Hull (*Proc.* R. I. A., Second Series, vol. iii. p. 161.)

non-linear terms of the equations of movement are not neglected, by M. J. Boussinesq. On the combination of free nitrogen with the elements of carbon disulphide, by M. Berthelot. (See Notes, p. 202.) A new combination of argon, its synthesis and analysis, by M. Berthelot. (See Notes, p. 202.) Preparation and properties of pure fused molybdenum, by M. Henri Moissan. Pure fused molybdenum has been obtained by means of the electric furnace. Its properties and reactions are very fully given in the paper. Among these it is stated to have a density = 9·01, to be as malleable as iron, and capable of being filed cold or forged hot. When heated in contact with carbon, it forms a steel by cementation much harder than the pure metal. It is suggested that molybdenum may be used in the Bessemer process in place of manganese, because it furnishes a volatile oxide disengaged in the gaseous state, and any excess of the metal remaining in the iron would be as malleable as the iron itself, and similarly capable of being hardened.—Action of phenyl isocyanate on campholic, carboxylcampholic, and phthalic acids, by M. A. Haller.—Discovery of a third permanent radiation of the solar atmosphere in the gas from cleveite, by M. H. Deslandres. The line of wave-length 706·55 has been obtained in the spectrum of cleveite gas, using a very luminous tube. This corresponds to a third permanent chromospheric line, leaving now only the green line 531·66—the coronal line not obtained from terrestrial sources. The new line corresponds with a line observed in the argon spectrum by the author, employing argon prepared by means of lithium. It bears out the suggestion of Prof. Ramsay, that argon and cleveite gas contain a common constituent. Comparative observations with declinometers of different magnetic moments, by M. Ch. Lagrange.—On the molecular transformations of chromic hydrate, by M. A. Recoura.—On some basic halogen compounds of the alkaline-earthy metals, by M. Tassilly.—Action of heat on the double alkaline nitrites of metals of the platinum group: Iridium compounds, by MM. A. Joly and E. Leidie. Among the products of the action of heat on potassium iridium nitrite, the author signalises the compounds: $6IrO_2.K_2O$, and $12IrO_2.K_2O$.—On the ammonium sodium acid tungstates, by M. L. A. Hallopeau. The compounds $16WO_3.3Na_2O.3(NH_4)_2O.22H_2O$ and $12WO_3.4Na_2O.(NH_4)_2O.25H_2O$ are described.—Rotatory powers of some amyl derivatives in the liquid and gaseous states, by MM. Ph. A. Guye and A. P. do Amaral.—On synthesised colloids and coagulation, by M. J. W. Pickering. Synthetic colloids behave, when injected into the vascular system, in a very similar manner to the nucleo-albumins.—On a new bed of "cipolin" in the rocks of the Central Plateau, by M. L. de Launay.—Glacial and fluvio-glacial deposits of the basin of the Durance, by MM. W. Kilian and A. Penck.—On the coexistence, in the basin of the Durance, of two systems of conjugate folds of different age, by M. Emile Haug.—On the Jurassic and Cretaceous systems in the Balearic Islands, by M. H. Nolan.—On the Miocene of the Novalaise Valley, by MM. J. Revil and H. Douxami. Researches on the sugar and glycogen in lymph, by M. A. Dastre. Lymph contains an appreciable quantity (0·007 per thousand) of glycogen, obtainable by the usual methods. Glycogen is destroyed in lymph, in less than twenty-four hours, by a diastasic ferment (lymphodiastase). Rohmann has shown the existence of a ferment of this kind in lymph. The glycogen appears to be entirely carried by the solid elements, and absent from the liquid plasma. The doctrine that sugar is the circulating form of carbohydrate is thus confirmed.—Modification of the heat radiated by the skin, under the influence of continuous currents, by M. Lecercle. Demonstration, by a new pupillometer, of the direct action of light on the iris, by M. Charles Henry. Experimental production of generalised ganglionary lymphadenoma in a dog, by M. Pierre Delbet. The author has proved the infectious nature of this disease, and has isolated the pathogenic bacillus causing it.—On serotherapeutics in cancer, by M. Paul Gabier. Details of serum injections in two cases of cancer and the consequent effects.—Kirghiz Island and its hydrological peculiarities, by M. Venukoff.—The recent earthquakes and their periodicity, by M. Ch. V. Zenger.

BERLIN.

Meteorological Society, May 7.—Prof. Hellmann, President, in the chair.—Dr. H. Meyer spoke on most probable and mean temperatures of the air. He showed by several examples (Berlin, Nertschinsk, Alexandria) that the values of the summit of the curve of frequency and of the arithmetic mean exhibit a relationship to each other which is dependent on cloudiness, and shows diurnal and annual periodicities which are of considerable importance for the characterising of climate. The same speaker next dealt with the applicability of Lambert's formula to the calculation of the average direction of the wind. He showed that later observers had neglected Lambert's presupposition that either the velocity or pressure of the wind must be introduced into his formula, and had employed the "frequency" instead, a fact which must lead to worthless results. But even when the formula is employed in accordance with Lambert's instructions the resultant direction arrived at has no climatic significance. A lengthy discussion ensued, which the President summed up as indicating that Lambert's formula was not generally regarded as sufficing for the calculation of the average direction of the wind. Only in the case where the movements of the air lie close together for a given period, and do not differ by more than 2°, does it appear at all profitable to calculate the resultant by means of this formula.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Garden Flowers and Plants: J. Wright (Macmillan).—Longmans' School Algebra: W. S. Beard and A. Telfer (Longmans).—Bulletin of the U.S. National Museum, No. 48. A Revision of the Deltoid Moths: Dr. J. B. Smith (Washington).—Heligoland as an Ornithological Observatory: H. Gatke, translated by R. Rosenstock (Edinburgh, Douglas).—An Introduction to Chemical Crystallography: Dr. A. Fock, translated and edited by W. J. Pope (Oxford, Clarendon Press).—Leitfaden for Histiologische Untersuchungen: Dr. B. Rawitz, Zweite Auflage (Jena, Fischer).—Das Pflanzenphysiologische Praktikum: Dr. W. Detmer, Zweite Auflage (Jena, Fischer).—Untersuchungen über die Starkekorner: Dr. A. Meyer (Jena, Fischer).—A Text-Book of the Science and Art of Bread-Making: W. Jago (Simpkin).—The Structure and Life of Birds: F. W. Headley (Macmillan).—Photography Annual for 1895 (Iliffe).—Exterior and Interior Photography: F. W. Mills (Dawbarn).—La Geologie Comparée: Prof. S. Meunier (Paris, Alcan).—Mind and Motion and Monism: Dr. G. J. Romanes (Longmans).

THE MOLUCCAS.

Reisen in den Molukken, in Ambon, den Uliassern, Seran (Ceram) und Buru. Eine Schilderung von Land und Leuten. Von K. Martin. Large 8vo. Pp. xviii. and 404, and volume of plates. (Leyden: E. J. Brill, 1894.)

THE Moluccas, the spice islands of the farthest east, were the most powerful magnets which drew the fleets of Portugal eastward around the Cape of Good Hope in the fifteenth century, and in the sixteenth induced Magellan to start on that voyage through his straits which culminated in the first circumnavigation of the globe. They were the most coveted lands on earth at the commencement of the history of modern discovery, the most eagerly sought for, first acquired, and the most firmly held of the colonies of Europe. Yet while the group has changed hands again and again without passing out of European ownership, the islands are still most imperfectly known. The system of exclusion which animated Portuguese, Spaniards, and Dutchmen alike, discouraged systematic exploration; and the works of such travellers as have recently made explorations in the islands, are for the most part locked up from the general reader in the Dutch language. In English, indeed, there is the matchless work of Wallace; but this, like several later English books on the Malay archipelago, is mainly concerned with the study of biological conditions.

Dr. Martin, the Professor of Geology in the University of Leyden, already well known for his admirable work on the Dutch West Indies, obtained a grant from his Government in 1891, and with a year's leave of absence proceeded to the study of some of the more interesting and less known islands of the Malay archipelago. Leaving Batavia on November 3, 1891, he coasted along Java, touched at Bali, visited various points on Celebes and Jilolo, making such geological and general observations as were possible in the limited time at his disposal. On November 27 he reached Amboyna, and until July 27, 1892, he devoted his whole time to detailed exploration, determining positions and heights, photographing scenery, people and houses, and collecting everything that came in his way in the islands of Amboyna, the Uliasser, Buru, and Ceram. In this way many places were visited which had never been adequately described before, several districts which had never been traversed by Europeans, and some which even the natives had avoided as sacred or unclean. The book is mainly geographical, going so far into the structure and vegetation of the land as is necessary in order to understand the life-conditions of the inhabitants, on whom also great attention is bestowed. Detailed reports on the geology, botany, the birds, insects, and other collections are being prepared by Prof. Martin and other specialists; but here he confines himself to the narrative of his expedition, with numerous explanations suggested by the preliminary results.

We so often find that books of travel are flabby masses of ill-upholstered padding, put together at second-hand by some big-game hunter or globe-trotter after his return, that we feel it a duty to call attention to the admirable form and substance of this one. It is of the order of Darwin's, Wallace's, and Bates' work, and though based on shorter experience than theirs, is none the less scientifically put together.

Prof. Martin says in his preface, that he gives a pure record of actual observations taken directly from his note-books and collections. After writing it, he proceeded to read up all the available literature on the subject, and took occasion in a series of footnotes to explain discrepancies or criticise his predecessors. In many respects this is an excellent method to pursue. The mind is free from prejudice or anticipation, and the observations bring the charm, and leave the stimulus of discoveries. On the other hand, unless what is known is previously worked up, there is apt to be much loss of time which could be more profitably spent, and points of the highest interest, being unsuspected, may pass unnoticed. We are inclined to believe, however, that, in spite of his modest disclaimer, Prof. Martin had a very good notion of what had been done before he entered the field. Otherwise he could scarcely have been so self-denying as to turn away from the people of Amboyna and the Uliasser, who have been fully studied by van Hoëvell, Joest, Riedel, and others, and give attention mainly to the features of the land. And in Ceram he knew very well where the coast-lines were faultiest on the maps, and the mountains and rivers scattered according to the freest fancy of the cartographer; for there he proceeded to fix positions and draw maps, while giving attention at the same time to general collecting and to the study of the people and their customs.

In view of the distrust which has gradually beset the aneroid when used for measuring heights, it is interesting to learn that the result of Dr. L. S. Siertsema's discussion of the numerous aneroid readings made on this journey is to show that it is, after all, an instrument of considerable precision for elevations well under 10,000 feet.

The book is to be welcomed as the thoroughly sound work of an experienced man of science, and as containing a notable contribution to our scanty knowledge of a most fascinating region, and of primitive peoples whose ancient customs are fast giving way before the pervading European influence. It suggests forcibly the importance of the study of regional geography in those places where the natural equilibrium of life and physical environment has not been disturbed; such places as are now scarcely to be found. It is exasperating to think that the careless traders and earnest missionaries who haunt the islands of the sea are every day rejecting sybilline books, the value of which seems likely to remain unsuspected, save to a handful of anthropologists, until the last of them is destroyed beyond recovery. The facts that primitive man must be studied at once if he is to be studied at all, and that purely natural floras and faunas are doomed to early disappearance from this planet, call for more workers like Prof. Martin, and demand them soon. The demand is for educated scientific explorers such as there is at present no means for training in this country. The day when geographical work of the first magnitude can be done by mere pluck and perseverance is almost past, and

the explorer of to-day must add to his enterprise scientific training, and to scientific training diligent study.

The contrast between the means of training for explorers in this country and on the continent, suggests many curious thoughts as to the proportion in which different countries will undertake the detailed study of the earth's surface in all its aspects, from which alone a true view of nature can be obtained. The theoretical training in geography only to be obtained in continental universities, and the practical training in the use of instruments and methods offered only by the Royal Geographical Society, are too far apart, and until they come together the general level of original work in unexplored countries will fall far short of the standard set by Prof. Martin. HUGH ROBERT MILL.

MILL ENGINEERING.

Steam Power and Mill Work. By George William Sutcliffe, M.Inst.C.E. (London: Whittaker and Co., 1895.)

THE Specialist Series of technical books is well known and appreciated; many subjects are admirably treated by well-known authors. The present volume, of some 800 pages, is no exception to this rule, and it fully maintains the high character of the series. In the preface we are told that this work aims at giving an account of modern practice for the consideration of those interested in the manufacture, control, and operation of boilers, engines, and mill work, also of the leading principles and calculations affecting such work, most of the subject-matter being based upon the personal experience of the author. Useful information has also been obtained from the minutes of proceedings of the leading technical societies and from various journals, adding considerably to the value of the book. Taken as a whole, this work will be of much use to steam users, particularly those employing steam power extensively with much machinery in operation.

It is impossible to notice in the space at our disposal the large amount of ground covered in this book. The author has arranged his matter in a sensible manner, and explains himself in a practical way. Many steam users are under the erroneous impression that the economical firing of a boiler is easily accomplished, that any labourer is capable of handling the shovel; to such men we recommend a careful perusal of this work, wherein they will discover that economical firing means more than they anticipated.

The author has much to say in chapter vi. on convection, circulation, evaporation, and priming in boilers. These points are thoroughly well discussed, being all-important to the life of the boiler and the comfort of the user. The estimation of the moisture in steam as delivered from the boiler is often necessary, and the difficulty of obtaining a true sample of the steam has to be met. Much useful information is given on this subject, and we would draw the attention of the author to an instrument designed by Prof. Watkinson, of Glasgow, which appears to give true results for the direct estimation of small quantities of water in steam.

The different methods of forced draught are discussed in the following chapter. The author, when describing the closed stoke-hole system, observes: "It is scarcely possible to imagine a case in which it would be wise to adopt a closed stoke-hole in stationary work." This is a very usual opinion held by engineers, who believe that most of the break-downs in the Navy, through leaky tubes, may be traced to this system of forced draught being adopted. The question of gas firing appears to be coming to the front for steam boilers in towns, for the prevention of smoke, and an increased economy in fuel. There is no doubt that a good deal can be said in favour of the system. The author has much useful information on the subject, particularly on the production of gas for the purpose. Liquid fuel, again, is another innovation in the way of raising steam. This system has reached its present state of perfection in the hands of Mr. Holden, the locomotive engineer of the Great Eastern Railway, who has successfully applied it to locomotives and stationary boilers.

The important subject of a pure water supply for steam boilers is pointed out in the following chapter. The effects of different impurities are described, besides the dangerous results involved by admitting grease into a boiler with the feed-water through contamination with the exhaust steam. Many furnaces have collapsed from this cause. We now come to the more mechanical part of the book, commencing with the construction and general fittings of Lancashire and Cornish boilers. Taken as a whole, the subject of boilers generally is fairly well dealt with. In the paragraph on internal flues, we find no description of Fox's corrugated flues, nor those of the Farnley Company; both are very commonly in use, and should have been mentioned. Under the head of "riveting" it might be well to point out that, although steel rivets are now the general rule when closed by machine, the few hand rivets necessary should in all cases be of Yorkshire iron. Caulking is now generally done by steam or pneumatic tools, the best of which is certainly Macewan Ross's patent, of Glasgow. Probably the most important fitting for a boiler is the glass-water gauge, and this should close automatically if the glass breaks. There are many of these in the market, more or less trustworthy; those supplied by Messrs. Dewrance and Co. being among the best. The author recommends the pendant syphon arrangement for fixing the pressure gauge to the boiler. This allows too much heat to reach the gauge through the heavy metallic fitting, and cannot be recommended for this reason. The locomotive type of stationary boiler is being largely used for steam raising: it is economical, easily set in position, and produces large quantities of steam when pressed.

Under the heading of "Types of Steam Engines," we find much information of a varied nature. The Willans central valve engine is, however, not described. This is a pity, because it is now being largely used for ordinary work, and gives great satisfaction. It is most economical, and will run for months without attention. The author goes into much detail when discussing valve arrangements for steam engines, commencing with the well-known "technical school" diagrams of slide valves with and without lap, &c., and ending with the piston valve; then follows double beat valves, Corlin valves, and many others. All these descriptions are clear and to the point.

Chapters xxiv. to xxxiv. may be said to contain descriptions of the construction and design of the principal parts of steam engines. Some formulæ are given, as well as a few maximum pressures allowable on the different parts. On page 428, the author says that the pressure of 80 lbs. per square inch of bearing surface is allowed in locomotive practice between the slide blocks and bars, *when both surfaces are of hardened steel*. It is not the usual practice to make the slide block surfaces of hardened steel, and in engines built years ago, the pressure per square inch very much exceeded this limit. In most recent practice with cast-iron bars and slide blocks, this limit may be safely used. The taking of indicator diagrams is always one of interest. Chapter xxv. deals very thoroughly with this subject. Trials in connection with the power and efficiency of engines and boilers naturally follow the indicator, and very complete instructions are given for carrying these out, including precautions in advance of the trial. The concluding chapters of this work deal principally with mill work in its many branches. Friction and lubrication are explained, and many valuaole hints are given. This book should prove of assistance to the steam user. The information given is of such a nature which will appeal to his partial knowledge of the subject, and render him more capable of understanding machinery generally.

N. J. L.

LECTURES ON DARWINISM.

Lectures on the Darwinian Theory. Delivered by the late Arthur Milnes Marshall, M.A., M.D., D.Sc., F.R.S., Edited by C. F. Marshall, M.B., B.Sc., F.R.C.S. (London: David Nutt, 1894.)

ALL the characteristics of the late Prof. Milnes Marshall are strikingly apparent in these lectures. In dealing with the many aspects of a subject which is often imperfectly understood, these lectures are clear and forcible, and the metaphors apt and convincing.

The first lecture deals with the history of the theory of evolution, and contains a concise and interesting epitome of the growth of this great conception, together with a brief account of the chief writers on the subject. The relationship between the process of evolution and the causes upon which it depends are perhaps liable to misinterpretation, the want of any feasible suggestion as to the latter being spoken of as a "fatal flaw" in, or a "fatal objection" to the former. Undoubtedly the want of some efficient cause at first prevented a wide belief in evolution, but logically the two questions are entirely distinct, and the evidence for evolution itself would stand undisputed, even if every one of the causes which now find acceptance were to be abandoned for ever. We know that Darwin himself was a convinced evolutionist long before his discovery of the principle of natural selection.

The second lecture treats of artificial and natural selection, and is accompanied by useful figures showing some of the changes which man has been able to accomplish in the creation of his domestic breeds. The whole lecture is clear and telling, the last paragraph being alone liable to possible misconception. In stating that "every species is for itself and for itself alone," it would have been advisable to bring forward instances in which a species benefits itself by benefiting others. It is most probable that such cases were described in the actual delivery of the lecture.

Then follow the arguments in favour of evolution, palæontology being first considered. We here meet, as in many of the other lectures, with exceedingly apt quotations from Darwin, Wallace, and others. It is an unfortunate omission that references are not given. In the delivery of the lectures to a general audience they may have been out of place, but there could have been no difficulty in their insertion in the present volume. Here, too, we find many useful figures of some of the extinct forms which are of the highest interest to the student of evolution. The reasons for the imperfection of the geological record are very excellently, and yet briefly, surveyed; and the same may be said of the sketch of the argument from geographical distribution, in which, however, by an obvious slip, the forest region of Brazil is spoken of as "south of the river La Plata" (p. 75).

The argument from embryology was probably the most congenial to the lecturer. This chapter is well illustrated, and contains more detail than the others. The term "acquired or larval characters" (p. 103) is open to exception, and the statement that rudimentary organs must be "inherited, for in no other way can their presence be explained" (*loc. cit.*), is too brief to be clear. It is probable that this sentence served as a note to be expanded by the lecturer; but it also required expansion by the editor. The chapter will be found extremely interesting and instructive by those who wish to read a popular account of the bearing of embryological facts upon the Darwinian theory.

The chapter on the colours of animals and plants, although containing much information in a little space, is not worked out in so complete and balanced a form as the other chapters, and in large part consists, apparently, of notes for the lecturer's use. It is erroneously stated that the colours of certain lepidopterous larvæ are due to their food, and some of the supposed examples of the direct action of environment are by no means proved to be caused in this way.

Then follows an interesting lecture on the "objections to the Darwinian theory." The figures of Pteropus on p. 165, although sufficient in themselves, are clumsily arranged. Here, too, many aspects of the subject are only treated in brief lecturer's notes, although these frequently contain trenchant remarks.

The "origin of vertebrated animals" is next considered, and the series concludes with an excellent epitome of "the life and work of Darwin."

It will be seen that the sequence of subjects is a very natural one, and well calculated to lead a general audience to follow and understand the most prominent and important aspects of the Darwinian theory.

E. B. P.

OUR BOOK SHELF.

My Climbs in the Alps and Caucasus. By A. F. Mummery. Illustrated. (London: T. Fisher Unwin, 1895.)

MR. MUMMERY is a bold man. Not only has he dared greatly among peaks and glaciers, but also he does not scruple to declare that he enjoys mountain

climbing for its own sake. He leaves science for others, cares nothing for topography except as ministering to his pastime, and holds a plane-table in abhorrence. Thus between his book and Sir W. M. Conway's "Climbing in the Karakoram Himalayas," there is a great difference. Still this is common to both: a delight in the wild beauty and silent grandeur of the crags, pinnacles and snows of the higher peaks. There is, no doubt, a beauty in the Alps which all the world can see, as Ruskin has truly remarked; but there is another aspect, solemn, almost stern, yet with a strange, thrilling fascination, which he only can appreciate who has grasped their rocky ledges, or planted his ice-axe in their unsullied snows. Vain it is to rebuke Mr. Mummery for treating the mountains like greased poles. He retorts, unabashed, that the pole is slippery, not greasy, and that he enjoys trying to climb it. But he seeks not to vulgarise the mountains; he has no love for the crowd of tourists which now annually deluges the Alps, nothing but contempt for the cockney "mountaineer" who is hauled up a peak by his guides, like a bale of goods, or who makes an ascent simply because it is "the thing to do." Perhaps Mr. Mummery may sometimes carry daring beyond the verge of rashness. It is to be hoped that few readers of this book will be tempted to follow his example of making difficult ascents without guides; for such work requires not only gymnastic skill, but also knowledge and judgment, which very few amateurs can ever acquire. Still it is difficult to avoid sympathising with his love of a struggle—it is the spirit which has made England great, a spirit which is too often lacking in this age of molluscous sentimentality and invertebrate opportunism.

Mr. Mummery's book, as we have said, contains no science and hardly any geography, but those who love the story of a plucky scramble, clearly told in good pithy English, will be loth to lay it down. It is well illustrated, with a number of small sketches introduced into the text, and eleven full-page pictures from either drawings or photographs. One or two of these will repay study as fine examples of the forms of weathered crags. None is better than the photogravure of the lower peak of the Aiguille Grépon. Among the expeditions described are two ascents of the Matterhorn by unwonted routes, a passage of the Col du Lion and Col des Courtes, ascents of the Teufelsgrat (written by Mrs. Mummery), of the Aiguilles des Charmoz, Grépon, du Plan, Verte (also by two unwonted routes), and of the Dent du Requin. The chapters on the Caucasus describe some fine excursions, the chief of which is the first ascent of the Dychtau (17,054 feet) in 1888, a magnificent peak, called in the *Alpine Journal* of that date Koshtantau, for apparently this and a slightly lower summit to the east (climbed by another party in the following year) indulge in a distracting habit of exchanging names. In a concluding chapter Mr. Mummery discusses various moot points in Alpine craft, advocating a preference for "two on a rope" in difficult places, a preference which is not likely to pass unquestioned by some of his brother climbers. T. G. Bonney.

Dairy Bacteriology. By Dr. Ed. von Freudenreich. Translated by J. R. Ainsworth Davis. (London: Methuen and Co., 1895.)

An English translation of Dr. Freudenreich's little book appears very appropriately at the present juncture, when serious efforts are at length being made to raise the standard of our dairy produce by providing special courses of study for those engaged in its production. Although some of the peripatetic instruction on dairy-work instituted in various districts by local County Councils has not been attended with the success anticipated, yet there can be no doubt that systematic training in this direction is very urgently required. As the translator truly remarks, "Not only Denmark, but America, France, Germany, and Switzerland are far ahead of us in these matters, and compete against home dairy products with only too much success, while Australia is rapidly becoming another serious rival." The information contained in "Dairy Bacteriology" as to the *scientific* origin of some of the troubles with which, in actual practice, the manufacturer of dairy produce is only too well acquainted, will doubtless be a revelation to many, whilst the instructions given for their successful elimination from the dairy, should at any rate impress the student with the hopelessness of attempting such delicate operations as are involved in dairy work without an adequate knowledge of the various parts played by bacteria in dairies.

The little volume is but an introduction to the subject, otherwise we should have been justified in expecting a better account of the milk-microbes which have been discovered; it is, however, written in an attractive manner, and the author has, moreover, succeeded in making it interesting and readable to the public generally, who as consumers are even more concerned than the manufacturers in the hygienic aspects of our dairy produce.

We note that an edition of this useful little manual has already appeared in French, Italian, and Hungarian, and it only remains for us to congratulate Prof. Davis upon the excellent manner in which he has translated it into English.

Longmans' School Algebra. By W. S. Beard and A. Telfer. Pp. 528. (London: Longmans, Green, and Co., 1895.)

So far as abundance of examples goes, this book is in advance of other text-books of algebra. There are as many as 5200 examples in the book, 500 of which are collected as miscellaneous examples at the end. Teachers who like to have plenty of material upon which to exercise their pupils' minds, will find that this volume satisfies their requirements. It seems hardly necessary, however, to include in a school algebra such a very large number of examples; in our opinion, the volume would have been improved by omitting many of them, and amplifying the very scanty descriptive text.

Fallacies of Race Theories as Applied to National Characteristics. By the late W. D. Babington, M.A. Pp. 277. (London: Longmans, Green, and Co., 1895.)

Mr. H. H. G. MacDonnell prefaces these collected essays with a brief statement of the views expressed in them. The late author contended that the mental and moral characteristics of nations are mainly the result of environment, and are not derived from ancestors by heredity. The transmission of physical characteristics is not taken into consideration, and the treatment throughout is more historical than scientific.

A Chapter on Birds. By R. Bowdler Sharpe, LL.D., F.L.S. Pp. 124. (London: Society for Promoting Christian Knowledge, 1895.)

Eighteen of our rare avian visitors, and their eggs, are brilliantly depicted by chromo-lithography in this attractive volume for lovers of birds. Dr. Sharpe's notes on the life-histories and natural relations of the different species, furnish instructive reading for young students of ornithology. Such a volume ought not, however, to be published without an index.

Nature in Acadie. By H. K. Swann. Pp. 74. (London: John Ball and Sons, 1895.)

From the observations of birds, insects, and other forms of life, made by the author while on a voyage to Nova Scotia, and diffusely recorded in this book, it is possible to find notes of interest to naturalists. A systematic list of the species of North American birds mentioned in the text, is given in an appendix.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Size of the Pages of Scientific Publications.

IT was with much surprise that we received the circular of the Royal Society stating that it had been decided to abandon the present size of its *Proceedings* in favour of royal octavo, accompanied by a voting card on the question of a similar change in the size of the *Transactions*. At the Oxford meeting of the British Association, a Committee was appointed, by Section A, to endeavour to secure greater uniformity in the sizes of the pages of the *Transactions* and *Proceedings* of all societies which publish mathematical and physical papers. In view of the report which that Committee will present shortly at Ipswich, it is much to be hoped that the Council of the Royal Society will take no immediate steps toward carrying their recommendations into effect.

A considerable degree of uniformity already exists. The present octavo size of the *Proceedings of the Royal Society* is very nearly the same size as the *Philosophical Magazine*, the *Report of the British Association*, the *Proceedings of the London Mathematical Society*, and of the *Cambridge Philosophical Society*, and many other publications. The *Annalen der Physik und Chemie* is so very little smaller, that reprints from it can be bound up with others from the afore-mentioned sources, without paring down their margins excessively. For papers involving long mathematics or large diagrams, the quarto size of the present *Philosophical Transactions* approximates to uniformity with the *American Journal of Mathematics*, the *Comptes rendus* of the Académie des Sciences of Paris, the *Cambridge Transactions*, the *Edinburgh Transactions*, and numerous other quarto *Transactions*, such as those of the Institution of Naval Architects.

It is very important that specialists in any branch of science should be able to collect, and bind together, reprints of papers on their own particular subjects, and such volumes are of permanent value as works of reference. So long as there are only two sizes to deal with—the above-mentioned quarto and octavo—there is little difficulty about this, but occasionally one comes across a paper of intermediate size, which cannot be bound up with either, and the collection is thus necessarily incomplete. It is hoped that the report, so shortly to be presented, will be a guide to authors of papers in indicating which publications to select, and which to avoid, if they desire to conform to the average standard sizes. Although the work of the Committee is at present confined to mathematical and physical papers, it might perhaps be of advantage that the matter should be discussed in, and representatives on the Committee appointed from the other Sections of the British Association as well. The question of changing the size of the *Proceedings* was recently discussed by the London Mathematical Society, but it was decided to retain the existing form, at any rate for the present, mainly on account of its uniformity with other publications. It will be most unfortunate if the Royal Society takes any retrograde step which may prevent the sizes of its *Proceedings* and *Transactions* from being adopted as the standards.

G. H. BRYAN,
SYLVANUS P. THOMPSON.

On the Minimum Theorem in the Theory of Gases.

YOU would oblige me by inserting the following lines in NATURE. The last remark made by Mr. Burbury points out, indeed, the weakest point of the demonstration of the H-theorem. If condition (A) is fulfilled at $t=0$, it is not a mechanical necessity that it should be fulfilled at all subsequent times. But let the mean path of a molecule be very long in comparison with the average distance of two neighbouring molecules: then the absolute position in space of the place where one impact of a given molecule occurs, will be far removed from the place where the next impact of the same molecule occurs. For this reason, the distribution of the molecules surrounding the place of the second impact will be independent of the conditions in the neighbourhood of the place where the first impact occurred, and therefore independent of the motion of the molecule itself. Then the probability that a second molecule moving with given velocity should fall within the space traversed by the first molecule, can be found by multiplying the volume of this space by the function f. This is condition (A).

Only under the condition, that all the molecules were arranged intentionally in a particular manner, would it be possible that the frequency (number in unit volume) of molecules with a given velocity, should depend on whether these molecules were about to encounter other molecules or not. Condition (A) is simply this. that the laws of probability are applicable for finding the number of collisions.

Therefore, I think that the assumption of external disturbances is not necessary, provided that the given system is a very large one, and that the mean path is great in comparison with the mean distance of two neighbouring molecules.

LUDWIG BOLTZMANN.

9 Tuerkenstrasse, Vienna, June 20.

Argon and the Kinetic Theory.

THE spectrum exhibited by argon undoubtedly shows that, under the conditions of the experiment, the molecules composing the gas are set into an intense state of vibration, while the ratio of the specific heats (5/3, about) shows, according to the equation $\beta = \frac{2}{3}\frac{1}{\gamma - 1}$, that $\beta = 1$, and therefore the gas is, as pointed out by Lord Rayleigh, monatomic, and cannot therefore be capable of vibrating. But there is, I think, a very simple explanation of this apparent contradiction, and that is, that the above equation is not true, and that it should be, as will be proved hereafter, $\beta = 3k(\gamma - 1)$, where k is very nearly 1 for argon and other so-called permanent gases. This latter equation gives 2 for the value of β in argon, a value easily understood.

The virial equation for smooth elastic spheres *of finite magnitude* is $\frac{3}{2}PV = \Sigma\frac{1}{2}mv^2 - \frac{1}{2}\Sigma Rr$; and since the resilience is unity and r finite, the term $-\frac{1}{2}\Sigma Rr$ cannot vanish. Now the term $\frac{3}{2}PV$ represents work or its equivalent of energy; hence the right-hand member of the equation must represent the same, and since the term $\Sigma\frac{1}{2}mv^2$ is obviously kinetic energy, or its equivalent of work, the term $-\frac{1}{2}\Sigma Rr$ must also represent work or energy. Now we can find the value of $\frac{3}{2}PV$ in terms of $\Sigma\frac{1}{2}mv^2$, as follows. Imagine a cube box so constructed that one side of each pair can be used as a spring to discharge any mass in contact with a velocity v. And suppose three smooth elastic spheres each of mass $\frac{M}{3}$ to be discharged by the three spring sides with the above velocity into the interior of the box. Then the work done on each mass will be $\frac{1}{2} \cdot \frac{M}{3}v^2$. Put this equal to PV and take V equal to the volume of the box. The total work done is evidently $3PV = \frac{1}{2}Mv^2$. If, instead of three elastic spheres, we imagine a very great number of very minute ones of the same total mass to be discharged by the spring sides with the same velocity, the energy will be the same as before, and the above equation will still be applicable; and the state of affairs now represented would be that of an ideal gas. But owing to collisions after first starting the velocities of the particles will vary, and therefore we must write the equation

$$3PV = \frac{1}{2}M\overline{v^2}; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where $\overline{v^2}$ is the mean square velocity of the particles. By hypothesis V has the same value in the above equation as in the virial equation; and P can be proved, *if necessary*, to have the same value in the two equations as follows.

If f = the *mean* acceleration or retardation, as the case may be, of the cr. of gr. of an elastic sphere impinging directly against a plane; then $ft = v$. Also $f = \frac{v^2}{2s}$, $\therefore t = \frac{2s}{v}$. Here t is half the time of impact, and v the velocity normal to the plane before and after impact. Now if it can be shown that the time taken by the spring side of our imaginary box to give the same velocity is the same as the above, then it is obvious that the mean pressures in the two cases must be identical.

Assume s^3 to be the volume of the cube box, then s^2 is the area of each side. Now let the spring side be drawn back so as to act through a distance s on the mass $\frac{M}{3}$ with a constant pressure P per unit of surface; then $Ps^2 \times s = PV$ represents the work done. The velocity given to the mass is v, and the acceleration constant. Hence the mean velocity of the spring

side in passing through the distance s is $v/2$, and the time is $s \div v/2 = 2s/v$, the same as in the first case. Which proves the proposition.

Since from (1) we have $3\ PV = \frac{1}{2}\ M\overline{v^2}$ or $\frac{3}{2}\ PV = \frac{1}{4}\ M\overline{v^2}$, we may substitute this value in the virial equation, and remembering that $\Sigma\frac{1}{2}mv^2 = \frac{1}{2}M\overline{v^2}$, we get $-\frac{1}{2}\Sigma Rr = -\frac{1}{4}M\overline{v^2}$. Hence also

$$P = \tfrac{1}{3}\,\rho\overline{v^2}\ .\ .\ .\ .\ .\ .\ .\ .\ .\ (2)$$

where $\rho = \frac{M}{V}$ the density. The above equation is easily obtainable without the use of the virial equation *when the time of impact* is taken into consideration. A phenomenon which cannot be assumed to be instantaneous without upsetting the dynamical definition of the measurement of a force; which expressed algebraically is $Ft = Mv$. From which it is evident that when t the time is 0, v the velocity, is also 0.

When the virial equation is made applicable to the case of a gas composed of molecules capable of vibrating, it seems obvious that the term $\Sigma\frac{1}{2}mv^2$ should be written $\Sigma\frac{1}{2}\beta m\overline{v^2}$; because, as shown by Clausius, the internal energy of the molecules bears a constant ratio to the energy of agitation. We must look to the *mechanical structure of the molecule* for the reason of this. Here the fact is simply accepted, not explained; but it is obvious that the same forces which impart translatory energy to a molecule will impart vibratory energy also. The same reasoning applies to the term $-\frac{1}{2}\Sigma Rr$, which now becomes $-\Sigma\beta(Rr)$. The volume of the gas is unaltered by the vibrations, and the pressure is dependent on the two other terms. Hence the equation may be written

$$\tfrac{3}{2}PV = \Sigma\tfrac{1}{2}\beta m v^2 - \tfrac{1}{2}\Sigma\beta(Rr)\ .\ .\ .\ .\ .\ .\ (3)$$

And from this we get

$$P = \tfrac{1}{3}\bar{\beta}\rho v^2\ \ .\ .\ .\ .\ .\ .\ .\ (4)$$

The above equation may be written

$$P_2 = \tfrac{1}{3}\rho v\bar{v}_i\ ;\ .\ .\ .\ .\ .\ .\ .\ .\ .\ (5)$$

Where $\bar{v}_i = \beta\bar{v}$. Again equation (2) may be written

$$P_i = \tfrac{1}{3}\rho_i v_i^2\ :\ .\ .\ .\ .\ .\ .\ .\ .\ .\ (6)$$

the suffix i denoting that the pressure, density, and mean square velocity are those of an ideal gas composed of smooth elastic spheres.

If P_i, ρ_i, and $\bar{v}_i$ in (6) are taken respectively equal to P, ρ, and v_i in (5); then it is evident that v_i in (5) is the velocity of mean square of an ideal gas which, having the same density, would give the same pressure as a natural gas. Hence v_i can be found from (6). Now the total energy in unit mass of a gas is given by the equation

$$K_v T = \tfrac{1}{2}\beta v^2\ :\ .\ .\ .\ .\ .\ .\ .\ .\ (7)$$

where K_v is the specific heat at constant volume, and T is the absolute temperature. From which equation $v\sqrt{\beta}$ can be found. We have also from above

$$v\beta = v_i\ \therefore\ \sqrt{\beta} = \frac{v_i}{v\sqrt{\beta}},\ .\ .\ .\ .\ .\ .\ (8)$$

from which equation the value of $\sqrt{\beta}$ and consequently β can be found.

The equation $\beta = 3k(\gamma - 1)$ can now be proved as follows. Multiplying both sides of (4) by V, the volume of unit mass, and combining with (7), we get

$$K_v T = 3PV\ .\ .\ .\ .\ .\ .\ .\ .\ (9)$$

Now from (5) and (6), taking $\rho = \rho_i$ we get $P = P_i/\beta$, and substituting in (9) $K_v = 3P_iV/\beta T$. But $P_iV/T = K_{ip} - K_{iv}$; or the difference between the specific heats at constant pressure and constant volume; the suffix i indicating, as before, that the symbols refer to an ideal gas. Hence

$$\beta = \frac{3(K_{ip} - K_{iv})}{K_v} = \frac{3k(K_p - K_v)}{K_v} = 3k(\gamma - 1)\ \ .\ (10)$$

Here k is some factor which for so-called permanent gases is very nearly unity. For such gases we may write (10)

$$\beta = 3(\gamma - 1)\ ;\ \text{or}\ \gamma = \tfrac{1}{3}(\beta + 3)\ \ .\ .\ .\ .\ (11)$$

In the following table the values of β, except in the case of argon, are calculated from equation (8); and $\bar{v}_i$, the velocity of ideal gases having the same pressure and density as their corresponding natural gases, at standard temperature and pressure, from (6). The velocities are given in feet per second, and the value of gravity is taken at 32·2. Column (4) gives the values of γ for the different gases calculated from equation (11); and column (5) gives the experimental values of γ. The close agreement between these values is a significant fact.

8, Norfolk Square, W., June 13. C. E. Basevi.

Romano-British Land Surface.—Flint Flakes Replaced.

In the early spring of the present year, whilst passing a newly-opened excavation near Caddington Church, three miles south-east of Dunstable, I noticed a very thin horizontal line of sharp flint flakes, embedded a foot deep from the surface-line of an old pasture. I could see at once that the line represented an old living surface, so I took a few of the flints away. In removing the stones from the soil, one or two little fragments of Romano-British pottery came away with them. The flakes were lustrous,

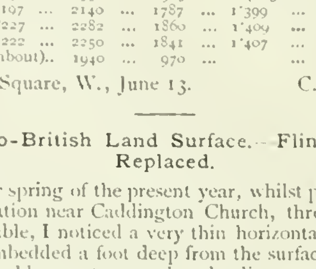

Fig. 1.—Fragment of perforated Romano-British pottery (half actual size).

chiefly black and brown-grey, and as sharp as when first struck. On looking over the flints in the evening, I was able to replace five on to each other. This fact, and the occurrence of the pottery fragments, proved the old surface to have remained intact from Romano-British times.

A little later in the spring, about six square yards of the superincumbent soil were carefully removed for me, when other flakes were found *in situ* to the exact number of four hundred; with these were eighteen fragments of Romano-British pottery, one piece—somewhat like the bottom of a pot—perforated, as here

Fig. 2. Four conjoined flint-flakes (half actual size).

illustrated. Amongst the flints were two cores, two hammer-stones, three scrapers, part of one edge of a chipped celt, and several neatly chipped but apparently unfinished little implements. A middle-brass Roman coin, too corroded for identification, was found on the same surface in a second excavation close by; with this was a small piece of wood carved to represent a horse's fore-leg, and a well-finished and perfect unpolished flint celt.

In sorting the flints I was able to replace thirty-eight on to each other in groups of from two to five. Two of these groups

are here illustrated—one a group of four, the other of two; the latter shows a straight-edged scraper above, conjoined to a simple flake below.

Hertfordshire conglomerate occurs as a surface stone at the same place, and I have at different times picked up very thin pieces without bulbs which appeared to me to have been artificially flaked. I have, however, kept no disputable objects. Hertfordshire "plum-pudding stone" was certainly flaked by the Kelts of this district, as is proved by the large, faceted and well-bulbed knife-like flake of conglomerate, found by myself at Caddington, here illustrated. This stone is not mentioned as one

FIG. 3. Straight edged scraper, conjoined to a flake (half actual size).

known to have been utilised for tools in the list given by Sir John Evans, in his "Stone Implements of Great Britain."

It is difficult to fix a date for the Romano-British living surface here mentioned, as the coin is too corroded for determination; but a correspondent, the Rev. Henry Cobbe, of Maulden, has a Roman coin, found in an adjoining field at Caddington, inscribed "C. CÆSAR AUG. GERMANICUS." If this inscription indicates the Emperor Caligula, as Mr. Cobbe believes, we have a date, A.D. 37–41, and the coin was probably brought over by one of the

FIG. 4. Large knife-like flake of Hertfordshire conglomerate (half actual size).

soldiers of Aulus Plautius under Claudius, in the second coming of the Romans in A.D. 43.

A short distance from the old land surface here described is an extensive Roman refuse pit with abundant broken pottery; so that it is safe to assume that a Roman villa once stood close by, and we seem to have evidence of the curious fact of a Kelt sitting down in close proximity to a Roman house and its refuse pit, quietly chipping his stone implements. It is equally curious that the implements and detached flakes have remained undisturbed so near the surface for nearly two thousand years.

Dunstable. WORTHINGTON G. SMITH.

The Bifilar Pendulum at the Royal Observatory, Edinburgh.

SOME interesting readings of the bifilar pendulum, designed by Mr. Horace Darwin for measuring movements in the earth's surface, were made here at noon on the 9th inst. This instrument, which indicates oscillations in a north and south direction, was erected in March of last year, and daily observation of it has since been carried on, the scale being read off each minute, from five minutes before to five minutes after Paris noon. On the 9th inst. nothing unusual was noticed during the first seven readings, these being all practically the same; but on putting my eye to the telescope for the eighth, I at once noticed that during the interval of less than a minute since the preceding reading, the mirror had rotated considerably about its vertical axis, the normal having moved towards the north, the difference between the seventh and eighth readings being no less than 7·6 mm. of the scale. An immediate examination of the lamp-stand showed it to be perfectly firm. After the regular daily readings were completed, others were made at intervals of generally two minutes, for half an hour after Paris noon. These showed two quite conspicuous oscillations of the mirror during its return to its original position, which it reached about thirteen minutes after noon. It continued to move beyond this point towards the south, till at 0h. 31m. Paris mean time it was 4·1 mm. south of the point at which the scale was first read off. Later readings in the course of the day showed that it was still moving slowly to the south, but no further oscillations were recorded. In the evening, when the mirror appeared to have come to rest, the sensitiveness of the instrument was tested, and with this the column headed "Tilt of mirror-frame" in the following table has been computed. The positive sign indicates a tilt to the north.

THOMAS HEATH.

Royal Observatory, Calton Hill, Edinburgh, June 20.

Migration of a Water-beetle.

LAST night, at about ten o'clock, a beetle flew in through the open window, alighting on a bowl of roses in the centre of the dining table. On being dropped into a finger-bowl he promptly dived and swam merrily, and proved to be a specimen of the ordinary brown water-beetle, to be found in every pond or ditch of water. Now the nearest water to my dining-room window is the Thames, distant over a quarter of a mile as the crow flies, whence this water-beetle must have flown. Can any of your readers inform me whether such long flights have been observed before in connection with the pairing season or migration of this species? I enclose you a rough sketch of the beetle, not knowing its specific title amongst the Coleoptera.

ROSE HAIG THOMAS.

Basildon, Reading, June 23.

ARGON AND HELIUM IN METEORIC IRON.

IN the light of the new discoveries of argon and helium, it appeared that the reinvestigation of the gas evolved on heating meteoric iron might promise interesting results. This anticipation has been fulfilled. Meteoric iron, heated *in vacuo*, yields a small amount of both argon and helium, besides a comparatively large quantity of hydrogen.

The investigation of gases occluded in meteoric iron was undertaken by Graham in 1867 (*Proc. R. S.*, xv. 502). From 45·2 grams of a specimen of iron from Lenarto, in Hungary, Graham obtained, by heating it *in vacuo*, 16·53 c.c. of gas, consisting of 85·68 per cent. of hydrogen, 4·46 of carbonic oxide, and 9·86 per cent. of "nitrogen." And eight years later, Prof. Mallet investigated the gases from a specimen of meteoric iron from Augusta County, Virginia, and found 35·83 per cent. of hydrogen, 38·33 per cent. of carbonic oxide, 9·75 per cent. of carbonic anhydride, and 16·09 per cent. of "nitrogen." (*Proc. R. S.*, xx. 365.)

In the same year, Prof. A. W. Wright examined spectroscopically the gases evolved from two meteorites, one the "great Texas meteorite" in the museum of Yale College, which weighs 742 kilograms; another a specimen of meteoric iron from Tazewell County, Tennessee; and a third set of experiments was made with fragments of a meteorite from Arva, in Hungary. The gases obtained were examined spectroscopically, and were found to show the usual spectra of hydrogen, carbon compounds, oxygen, and nitrogen. He was searching for lines present in the spectra of stars, but found none; and he concludes that the spectrum of the solar corona is to be ascribed merely to atmospheric gases. A preliminary account of the examination of a fourth (a stony) meteorite is given in the same journal (*Amer. Journal of Science* [3], ix. pp. 294 and 459), and the full account in vol. x. 44. Suffice it to say that the last fractions of gas evolved contained 6·91 per cent. of "nitrogen." On p. 257 of the next volume (xi.), Prof. Wright gives analyses of the gases from various samples of meteorites, which contain from 1·54 to 5·38 per cent. of "nitrogen." And lastly, in vol. xii. p. 165, he gives further details, including descriptions of spectra, in none of which he noticed anything unusual.

Prof. Wright's interesting papers are instructive, inasmuch as they show how little reliance is to be placed on the evidence of the spectroscope as to the presence of any one gas in a gaseous mixture consisting of a large proportion of other gases. There is no doubt that in future, much attention should be paid to the relative conductivity of gases. The characteristic spectrum of argon is almost completely masked by the presence of a few parts per cent. of nitrogen or of hydrogen; and that of helium is similarly affected, although to a less degree. Though no quantitative experiments have been made on the subject, yet I should judge that the presence of from 5 to 10 per cent. of nitrogen entirely obscures the characteristic yellow line; the other strong lines still remain visible. I hope soon to be able to communicate further information on this interesting subject.

The presence of both argon and helium has been demonstrated in the meteorite from Augusta County, Virginia, a sample of which was purchased from Mr. Gregory. Two ounces of turnings of this meteorite were heated to bright redness in a hard glass tube, all air having been first removed in the cold by a Töpler's pump. From this iron, 45 c.c. of gas were obtained. It was mixed with oxygen in a gas burette, and exploded. It appeared to consist for the most part of hydrogen. After absorption of any carbon dioxide and the excess of oxygen with alkaline pyrogallate, the residue amounted to about half a cubic centimetre. It was transferred to a small tube and dried with a morsel of solid caustic potash, and with it several vacuum tubes were filled. The spectrum showed that it consisted for the most part of argon; the trace of nitrogen which appeared at first rapidly disappeared under the influence of the discharge.

The spectrum was carefully compared with that given by a tube of atmospheric argon, provided with magnesium electrodes. This sample of argon always shows the D lines of sodium, owing to the magnesium electrodes, and proves especially convenient for the detection of helium, the yellow line of which is not coincident with the lines of sodium. Both spectra were thrown into a two-prism spectroscope at the same time, and on careful comparison it was evident that all the argon lines were present. Besides these, the yellow line D_3 of helium was faintly visible, not coincident with the sodium lines; and on comparing the spectrum of the gas directly with that of helium from cleveite, it was possible to recognise the identity of the red, blue-green, blue, and violet lines of helium in the meteoric gas. No other lines were visible than those of argon and helium. It may thus be concluded, on spectroscopic evidence, that both argon and helium are contained in meteoric iron, the former in much larger amount than the latter. This conclusion was verified by mixing about 90 per cent. of argon with 10 per cent. of helium. The spectrum of helium, under these circumstances, was much more brilliant than that of argon; hence it may be concluded that less than 10 per cent. of this gaseous residue consisted of helium.

It appeared likely that metallic iron might be induced to absorb argon. It had been noticed, last October, that in attempting to prepare argon by passing atmospheric nitrogen through iron tubes filled with magnesium turnings, and heated to redness, a smaller quantity of argon than usual was collected. This rendered it not improbable that iron at a red heat is permeable to argon. If permeable, then it might be permanently absorbed. An experiment was therefore undertaken by Mr. Kellas, to whom I have to express my indebtedness, to ascertain whether finely divided iron, obtained by the reduction of ferric oxide in hydrogen, would occlude argon.

About 14 grams of the finely divided iron was placed in a combustion-tube, the capacity of which was 53·6 c.c. The tube was connected by a three-way stopcock to a Sprengel's pump and to a water-jacketed reservoir containing argon over mercury. After exhausting the tube, argon was allowed to enter, and the temperature was slowly raised to 600° and maintained for three hours. Until equilibrium of temperature had been established, no perceptible change of volume could be noted. The tube was allowed to cool, connection with the argon reservoir was closed, and the gas was pumped off. The volume, corrected for temperature and pressure, was 54·2 c.c. On heating the tube, about 59 c.c. of gas was given off; it was collected in three fractions, (*a*), (*b*), and (*c*), the heating having been continued for twelve hours.

(*a*) The volume of this gas was 30 c.c. It was collected at about 200° C. This was exploded with oxygen; and a residue was obtained, of which the greater part dissolved in caustic potash, showing that the gas had consisted of hydrogen and hydrocarbons. The final residue was 1·7 c.c.

(*b*) The second fraction, collected at 450°, amounted to 15 c.c., and after treatment as above, the residue was 0·25 c.c. This residue was united with that from (*a*), and a vacuum tube was filled. The flutings of carbon were visible, and also a trace of hydrogen, but no argon. This gas was sparked with 1 c.c. of oxygen, and on absorbing the excess of oxygen with alkaline pyrogallate, 0·45 c.c. remained. On transferring this residue to a vacuum tube, the banded spectrum of nitrogen was alone visible.

(*c*) The third fraction, collected at a red heat, also showed only the spectrum of nitrogen, when purified and transferred to a vacuum tube, and on continuing the discharge it also disappeared and the tube became

phosphorescent. Judging from previous experience, the presence of argon would have revealed itself after the nitrogen had disappeared. It may therefore be concluded that whether iron is permeable to argon at a red heat or not, it does not permanently retain the gas. It is not improbable that the condition of retention may be that the iron is heated to fusion in an atmosphere of hydrogen, hydrocarbons, argon, and helium, and that it is then suddenly cooled. This I should imagine to be the case if the iron were ejected from some stellar body at a high temperature. I am, however, unaware whether any of the lines of the argon spectrum have been identified in the spectra of stars; if not, it is probably because they are masked by the spectra of hydrogen and carbon.

W. RAMSAY.

SUBTERRANEAN FAUNAS.

THE researches of geologists and engineers have revealed the existence of vast tracts of underground waters, often associated with more or less extensive caves. The investigation of these underground waters is interesting to naturalists, as it has led to the discovery of a special subterranean fauna, different in different regions, it is true, but characterised throughout by modifications in certain definite directions. The study of these modifications is a fascinating one, and the problem of their evolution seems to be rendered comparatively easy by the simplicity and limitations of the conditions of life which obtain beneath the earth's surface; for these subterranean forms live in continual darkness, and are exposed to a fairly uniform temperature at all times. It is also, in many cases, possible to tell from what surface-species an underground form has descended, and to infer the age of the latter with a fair approach to accuracy; the nature of the changes undergone, and the rate at which these modifications have taken place, can thus be estimated in particular instances.

It will be remembered that in Packard's well-known memoir on the Cave Fauna of America, the peculiar modifications of subterranean animals were interpreted as lending strong support to the theory of the inheritance of acquired characters. Recently, however, in a careful and interesting memoir on the subterranean Crustacea of New Zealand (*Trans. Linn. Soc.*, London, vol. vi., 1894), Dr. Chilton considers the question from the Neo-Darwinian aspect; and he adduces a number of facts and arguments which greatly tend to reduce the force of Packard's contentions.

Dr. Chilton begins his memoir with a completed account of the New Zealand subterranean Crustacea, including a description of some new species. The underground crustacean fauna of New Zealand has a more varied aspect than that of Europe or North America; of the six species known, three are Amphipods and three Isopods, and these belong to as many as five different genera. Among them *Gammarus fragilis* is interesting to us as being allied to the blind *Niphargus* of Europe. *Cruregens fontanus*, an Isopod belonging to the family Anthuridæ, is curious in possessing only six pairs of legs; the seventh segment is small and without appendages, as is the case also in young Isopods; this larval character is retained in *Cruregens*, probably owing to an arrest in development on account of the scanty supply of food. Two subterranean species of the genus *Phreatoicus* are described, *P. typicus* and *P. assimilis*, n. sp.; a surface species, *P. australis*, lives on the top of Mount Kosciusko in Australia. This genus is peculiar, and the type of a new family of Isopods which approaches the Asellidæ in some respects, but differs in the possession of a laterally compressed body and a long six-jointed pleon.

In addition to the description of these underground forms, the writer gives a *résumé* of our only too scanty knowledge of the habits and conditions of life of subterranean animals. He discusses also the question of the origin of cave forms, and arrives at the conclusion that the New Zealand subterranean crustacea have clearly been derived from a surface fauna, though the affinities of one or two species seem to be rather with marine than with known fresh-water forms. It is pointed out, however, that the cave fauna is not necessarily descended from the present surface fauna of the country; *Crangonyx compactus*, for instance, has its nearest allies in Europe and North America, and the remarkable habitat of the fresh-water species of *Phreatoicus* has already been mentioned.

Cave crustaceans, according to Packard, live "in a sphere where there is little, if any, occasion for struggling for existence between these organisms." Chilton, however, suggests that there is evidence for thinking that Natural Selection has come into play in the evolution of cave animals. He points out that the scanty supply of food must inevitably lead to a keen struggle. Moreover, Packard himself states that the *Cæcidotea* and *Crangonyx* of the North American caves are eaten by the blind crayfish, which in its turn is devoured by the blind fish *Amblyopsis*; so that these animals must struggle with their destroyers. To this end have probably been developed the additional olfactory setæ, described by Packard and others, to enable the pursued animals to escape from their enemies. If there were no occasion for struggling for existence, why should these additional sense organs have been developed at all? At first sight, it certainly seems natural to attribute the degeneration of the eyes, observed in underground forms, to disuse; and it is but a further step to assume that these new characters, resulting from disuse and adaptation to new conditions of life, were inherited by successive generations. But Chilton ingeniously remarks that, if the modifications in the eyes of cave animals were the direct inherited effect of the environment, we should expect to find the lines of modification similar in all animals subjected to the same conditions. This, however, is not the case, as Packard's own investigations have shown. The influences leading to degeneration act uniformly on all individuals, but the modifications produced in the eyes are various, and occur in different ways. In some cases there is total atrophy of the optic lobes and optic nerves, with or without the persistence in part of the pigment (or retina) and the crystalline lens; in others the optic lobes and optic nerve persist, but there is total atrophy of the rods and cones, retina, and facets; while in extreme cases there is total atrophy of the optic lobes and nerves, and all the optic elements. These examples, showing a development apparently capricious and varying in direction in animals all subjected to the same or similar environment, point rather to the action of Natural Selection than to that of the direct inherited influence of the conditions of life.

In a more recent essay in the *American Naturalist* (September 1894), Packard has restated his views on the subject of the modifications of the eyes in subterranean animals, and concludes his remarks with the following words: "That while the heredity of acquired characters was, in the beginning, the general rule, as soon as the congenitally blind preponderated, the heredity of congenital characters became the normal state of things." In support of his view, Packard cites some statistics upon the inter-marriage of deaf-mutes, which have been recently furnished by Prof. Graham Bell. It would appear that, in America at any rate, the segregation of deaf-mutes within asylums has been followed by a striking increase in intermarriages among them; so that, of the deaf-mutes who marry at the present time, no less than 80 per cent. marry deaf-mutes. A marked increase in the number of the deaf-mute population has ensued, and

Prof. Bell points out the danger which consequently exists of the formation of a distinct deaf-mute variety of mankind.

All this is clearly brought out in Prof. Bell's memoir; but Mr. Packard goes so far as to state that Mr. Bell's statistics appear to "almost demonstrate the fact of the transmission of characters acquired during the life-time of the individual," and also says that "deaf-mutes already appear to breed true to their incipient strain or variety, whether congenitally deaf *or rendered so by disease during the life-time of either or both parents*." (The italics are ours.) We are thus left in no doubt as to Mr. Packard's interpretation of Mr. Bell's researches; but an attempt on our own part to find in Mr. Bell's pages the particular statistics or remarks which may be regarded as all but demonstrating the inheritance of acquired characters has, remarkably enough, been completely unsuccessful. Mr. Bell's conclusions lend no support to such a view. So far as they bear upon the present subject, they are briefly as follows: (1) That the great factor in determining the production of deaf-muteness in offspring is the existence of a hereditary taint in the direction of deaf-muteness in one or both branches of the family. (2) That this hereditary taint is not the less potent in its effects if it fails to manifest itself in the actual parents of the deaf-mute. (3) That "non-congenital deafness, if sporadic, is little likely to be inherited."

It would thus appear, both from Chilton's presentation of the facts, and from the failure of Packard's appeal to analogy, that—often as the contrary opinion has been urged—the peculiarities of cavernicolous animals do not lend any particular degree of support to the Lamarckian principles of evolution. W. G.

PROPOSED BALLOON VOYAGE TO THE POLE.

DURING the last century many expeditions to the North Pole have been undertaken, but with no result so far as reaching it is concerned. Baron Nordenskiold, the great Arctic explorer, has made four expeditions to Spitzbergen, and two to Nova Zemlia and Greenland, besides having taken part in the celebrated voyage of the *Vega*. In all explorations both he and others have found the icebergs the chief obstacle; and it may be said that Arctic explorers are now almost all unanimously convinced that the Pole can never be reached in steamer or sledge. Attempts on foot have likewise failed, for the distance of about ten miles has never been exceeded, owing to the great difficulties and dangers.

Notwithstanding these facts, Dr. Nansen, the celebrated Norwegian explorer, attempted yet another way, and instead of cutting a path through the ice, he has allowed himself to be carried polewards by a northerly current. This took place a year and eight months ago, and he has not been heard of since.

Quite recently, at the Royal Academy of Science, Stockholm, an even more perilous project was proposed by M. Andrée, a Swedish engineer. M. Andrée proposes making the expedition in a balloon. The project is not a new one, but it has never been seriously discussed by Arctic explorers. M. Andrée, however, has had much experience in polar regions, having spent the winter of 1882–83 in the far north, and also taken part in the Swedish Meteorological Expedition, which lasted a year. He has also proved himself to be a dauntless aeronaut, his most interesting voyage being one from Gothenburg to the Isle of Gothland, in which he had to cross part of the Baltic. Everything in connection with this proposed expedition has been minutely studied and discussed; and infinite pains have been taken to solve all difficulties.

The balloon would require a double outer covering, and a volume of 6500 cubic yards. The ascensional power thus obtained would be sufficiently great to carry three persons, furnished with provisions for four months, besides allowing for the car being fitted up with necessary instruments for observation, life-buoys, and Berton's collapsible boats. The car could be suspended in such a way as to allow of instant detachment in case of a descent into the sea. The entire weight of the balloon must not exceed about three tons. In the instance of Henri Giffard's captive balloon, exhibited in 1878, and which weighed about six tons, it only required newly inflating after a year's use. According to Graham's observations, a balloon measuring 8¾ yards in diameter can be made sufficiently air-tight so as to suffer, per month, merely a loss of 13½ lbs. of its ascensional force. M. Andrée, however, hopes to produce an absolutely impermeable covering.

The balloon, being protected from the wind by a wooden enclosure, would be inflated as far north as possible, by means of hydrogen compressed in cylinders. This once accomplished, it would begin to ascend. To a certain extent it might be steered by means of a sail and several guide-ropes, which, dragging on the earth, form as it were a brake. The ropes, however, would have to be of special composition, in order to produce the same effect in water. The hindrance thus caused to the flight of the balloon, together with the pressure of the wind, would allow the use of a sail. The flight then might reach an angle of 40° away from the wind direction. This steering apparatus, invented by M. Andrée, has often been used by him in his aerial voyages.

Besides the guide-ropes, heavy lines, on which would be placed numbered metal plates, would be attached to the car; these would serve as ballast. In case of a lowering of temperature, and a consequent descent of the balloon, it could be lightened by throwing off these plates, which, if found, would, to a certain extent, show the course taken by the explorers.

Spitzbergen has been chosen as the starting-point, for this island is almost always clear of ice by the middle of June. The departure would take place in July, on a clear day, with a southerly wind. At Spitzbergen the average rate of wind per second is 10¾ yards; the guide-ropes would cause a hindrance of about 2¾ yards per second, therefore the average rate of balloon would be nearly 8 yards per second, which is about 16 miles an hour. At this rate the Pole should be reached in 43 hours.

The summer is in all respects the most suitable time for an aeronautic voyage in Spitzbergen. The lowest temperature observed at Cape Thordsen in July, 1883, was $+0^{\circ}.8$ C., and the highest $+11^{\circ}.6$ C. The movements of the balloon would therefore be very regular. Besides this, there are practically no storms, and the fall of snow in June and July is both slight and rare.

M. Andrée's project has been highly approved of by the most experienced Arctic explorers. Baron Nordenskiöld has declared himself in favour of it, and M. Eikholm, chief of the Swedish Meteorological Expedition to Spitzbergen in 1882–83, states that the conditions of the Arctic regions are most favourable for this voyage. He thinks, moreover, that in the future the balloon will be the principal means of exploring that part of the world.

For many of the above details, we are indebted to an article in the *Revue Scientifique*, by M. Charles Rabot. W.

THOMAS HENRY HUXLEY.

WE regret to announce that, after an illness extending back to last March, and relieved only by two or three brief periods of improving health, Prof. Huxley passed peacefully into the silence of death on Saturday afternoon.

So long ago as 1874, a notice of the life and work of Prof. Huxley was included in our "Scientific Worthies" (vol. ix. p. 257), and Dr. Ernst Haeckel added to it an appreciative notice of his biological labours. These twenty-year-old publications render it unnecessary that any extensive reference to the subject-matter of them should be given now, and, moreover, the chief details of his life are well known.

Huxley was born at Ealing in 1825. His scientific training began in the medical school attached to Charing Cross Hospital, which he entered in 1842. Four years later he joined the medical service of the Royal Navy, and proceeded to Haslar Hospital; from there he was selected to occupy the post of Assistant-Surgeon to H.M.S. *Rattlesnake*, then about to proceed on a surveying voyage in the Southern Seas. The ship sailed from England in the winter of 1846, and returned to England in 1850, after surveying the inner route between the Barrier Reef and the East Coast of Australia and New Guinea. During this period, Huxley sent home several papers, some of which were published in the *Philosophical Transactions* of the Royal Society. His first important paper, "On the Anatomy and Affinities of the Medusæ," was published in 1849. His communications, and the evience of ability which they furnished, led to his election into the Royal Society in 1851.

In 1854, Huxley succeeded his friend Edward Forbes as Palæontologist and Lecturer on Natural History at the Royal School of Mines, a post which he held until his retirement in 1885. He was a great teacher, and the high reputation of the School, now combined with the Royal College of Science, is largely due to his great influence. At the request of the Lords of the Committee of Council on Education, he continued to act as Honorary Dean of the School, and at death he still retained that post. He also agreed to be responsible for the general direction of the biological instruction in the School, so that his place as Professor of Biology has never been filled up.

Huxley was twice chosen Fullerian Professor of Physiology to the Royal Institution, the first time in 1854. In the same year he was appointed Examiner in Physiology and Comparative Anatomy to the University of London. Other posts and honours were crowded upon him. In 1858 he delivered the Croonian Lecture of the Royal Society, when he chose for his subject the "Theory of the Vertebrate Skull." From 1863 to 1869 he held the post of Hunterian Professor at the Royal College of Surgeons. In 1862 he was President of the Biological Section at the Cambridge meeting of the British Association, and eight years later held the Presidency of the Association at the Liverpool meeting. In 1869 and 1870 he was President of the Geological and Ethnological Societies, and in 1872 was elected Lord Rector of Aberdeen University for three years. As might be expected, Prof. Huxley held strong and well-defined views on the subject of education. He was a man who at all times had a keen sense of public duty, and it was this which induced him to seek election on the first London School Board in 1870. Ill-health compelled him to retire from that post in 1872, but during his period of service as chairman of the Education Committee he did much to mould the scheme of education adopted in the Board Schools.

He was elected Secretary of the Royal Society in 1873, and ten years later was called to the highest honorary position which an English scientific man can fill, the presidency of that Society. During the absence of the late Prof. Sir Wyville Thomson with the *Challenger* Expedition, Huxley, in 1875 and 1876, took his place as Professor of Natural History in the University of Edinburgh. From 1881 to 1885 he acted as Inspector of Salmon Fisheries. But this and all his other official posts he resigned in 1885, shortly after which he removed to Eastbourne.

In 1892, more than six years after his retirement, the dignity of Privy Councillor was conferred upon him. The Copley Medal of the Royal Society was awarded to him in 1888, the Royal Medal having been received by him in 1852; and in December last he received the Darwin Medal, the two previous recipients being Dr. A. R. Wallace and Sir Joseph Hooker. His honorary degrees were:—D.C.L. (Oxford); LL.D. (Cambridge, Edinburgh, and Dublin); M.D. (Würzburg; Ph.D. (Breslau). The King of Sweden created him Knight of the Polar Star, and he was elected into most foreign Societies and Academies of Science of note. He was a Correspondant of the Paris Académie des Sciences (Section of Anatomy and Zoology), and Corresponding Member of the St. Petersburg Académie Impériale des Sciences, the Akademie der Wissenschaften, of Berlin and of Munich, the Svenska Vetenskaps-Akademie, Stockholm, the Halle Akademie der Naturforscher, the Academies of Natural Sciences of Philadelphia, Boston and Buffalo, the Göttingen Gessellschaft der Wissenschaften, the Paris Société d'Anthropologie, and the Naturforschende Gessellschaft at Frankfurt-a-M. He was Honorary Member of the Royal Irish Academy, the Accademia dei Lincei at Rome, the Brussels Académie de Médecine, the Institut Egyptien at Alexandria, the Batavia Genootschap van Kunsten en Wetenschappen, the American Academy of Arts and Sciences, National Academy of Sciences, and the Amsterdam Akademie van Wetenschappen. He was also Foreign Member of the Brussels Académie des Sciences, the Haarlem Maatschappij der Wetenschappen, the Philadelphia Academy of Natural Science, and the Società Italiana delle Scienze.

How far-seeing Huxley was, with regard to our present scientific needs, may be gathered from his address when he retired from the presidency of the Royal Society. He saw that scientific literature would have to be organised before it could be fully utilised. His words were: "We are in the case of Tarpeia, who opened the gates of the Roman citadel to the Sabines, and was crushed under the weight of the reward bestowed upon her. It has become impossible for any man to keep pace with the progress of the whole of any important branch of science. . . . It looks as if the scientific, like other revolutions, meant to devour its own children; as if the growth of science tended to overwhelm its votaries; as if the man of science of the future were condemned to diminish into a narrower and narrower specialist as time goes on. . . . It appears to me that the only defence against this tendency to the degeneration of scientific workers, lies in the organisation and extension of scientific education, in such a manner as to secure breadth of culture without superficiality; and on the other hand, depth and precision of knowledge without narrowness." Another point touched upon in the same address was the claims of science to a place in all systems of education. "We have a right," he said, "to claim that science shall be put upon the same footing as any other great subject of instruction, that it shall have an equal share in the schools, an equal share in the recognised qualification for degrees, and in University honours and rewards. It must be recognised that science, as intellectual discipline, is at least as important as literature, and that the scientific student must no longer be handicapped by a linguistic (I will not call it literary) burden, the equivalent of which is not imposed upon his classical compeer." To the expression of such views as these we owe the increased attention now given to scientific instruction in this country, though we have not yet reached the impartial stage to which science has a right.

It may, perhaps, be too early to fix Huxley's real place in Biology. Writing in these columns in 1874, the eminent German naturalist, Haeckel, ranked him among

the first zoologists in England, taking zoology in its widest and fullest signification. "When we consider," he remarked, "the long series of distinguished memoirs with which, during the last quarter of a century, Prof. Huxley has enriched zoological literature, we find that in each of the larger divisions of the animal kingdom we are indebted to him for important discoveries." From the lowest animals he gradually extended his investigation to the highest. In the Protozoa, he was the first to come to satisfactory conclusions concerning the nature of Thalassicollidæ and Sphærozoida; and by his work on "Oceanic Hydrozoa," he greatly extended the knowledge of Zoophytes. His researches upon members of the important group of Tunicata are of great value, and many important advances in the morphology of the Mollusca and Arthropoda are due to him. Further, Huxley especially studied and advanced the knowledge of the comparative anatomy and classification of the Vertebrata. His "Lectures on the Elements of Comparative Anatomy," and his numerous monographs on living and extinct species, afford abundant evidence of what biological science owes to him.

Huxley's place as one who has largely influenced modern thought on many questions, is acknowledged by all to be a very high one. The profound and truly philosophical conceptions which guided him in his inquiries, always enabled him to distinguish the essential from the unessential. First among the subjects which owe their advancement to his support is the theory of biological evolution. When, in 1860, it became his duty as Professor at the Royal School of Mines to give a course of lectures to working men in the Jermyn Street Museum of Practical Geology, he selected for his subject "The Relation of Man to the Lower Animals." The questions arising out of this topic became the subject of warm controversy at the meeting of the British Association in that and subsequent years. The lectures were published in 1863, under the title "Evidence as to Man's Place in Nature," and excited great interest both in this country and abroad. In this and in other works he advanced the principles of the Darwinian theory, and worked out many important developments.

To again quote Haeckel: "Not only has the Evolution Theory received from Prof. Huxley a complete demonstration of its immense importance, not only has it been largely advanced by his valuable comparative researches, but its spread among the general public has been largely due to his well-known popular writings. In these he has accomplished the difficult task of rendering more fully and clearly intelligible to an educated public of very various ranks, the highest problems of philosophic biology. From the lowest to the highest organisms, he has elucidated the connecting law of development. In these several ways he has rendered science a service which must ever rank as one of the highest of his many and great scientific merits."

As a writer of English, Huxley has been unsurpassed in our time and generation. He has set a standard in scientific literature, both in clearness of exposition and in the most perfect handling of words, which it behoves his successors to closely follow. He aimed at writing clearly, and avoided the use of technical language whenever possible. As he remarks in the preface to the volume of "Collected Essays" containing his biological and geological addresses: "I have not been one of those fortunate persons who are able to regard a popular lecture as a mere *hors d'œuvre*, unworthy of being ranked among the serious efforts of a philosopher; and who keep their fame as scientific hierophants unsullied by attempts—at least, of the successful sort—to be understanded of the people. On the contrary, I found that the task of putting the truths learned in the field, the laboratory and the museum, into language which, without bating a jot of scientific accuracy shall be generally intelligible, taxed such scientific and literary abilities as I possessed to the uttermost; indeed, my experience has furnished me with no better corrective of the tendency to scholastic pedantry which besets all those who are absorbed in pursuits remote from the common ways of men, and become habituated to think and speak in the technical dialect of their own little world, as if there were no other."

This Journal especially loses in him one of its best friends. We are now in the second series of fifty volumes, and his was the hand that commenced both of them. His introduction to the fifty-first volume will be fresh in the minds of our readers, and it justified the position he had occupied since 1859, as the devoted apostle of the Darwinian theory. He was, moreover, not only a most valued contributor to our columns, but his advice on many points has been freely asked, given, and followed, during a quarter of a century.

Huxley's wonderful kindness to young men is very well known. He would discuss subjects with his students, and his perfect geniality put them entirely at their ease. Always ready to extend a helping hand, he assisted many to higher ranges than they could otherwise have attained, and by words of encouragement induced others to continue their ascent.

The objects which Huxley stated he had in mind from the commencement of his scientific career are these:—

"To promote the increase of natural knowledge and to forward the application of scientific methods of investigation to all the problems of life to the best of my ability, in the conviction which has grown with my growth and strengthened with my strength that there is no alleviation for the sufferings of mankind except veracity of thought and of action, and the resolute facing of the world as it is when the garment of make-believe by which pious hands have hidden its uglier features is stripped off. It is with this intent that I have subordinated any reasonable, or unreasonable, ambition for scientific fame, which I may have permitted myself to entertain, to other ends; to the popularisation of science; to the development and organisation of scientific education; to the endless series of battles and skirmishes over evolution; and to untiring opposition to that ecclesiastical spirit, that clericalism, which in England, as everywhere else, and to whatever denomination it may belong, is the deadly enemy of science. In striving for the attainment of these objects, I have been but one among many, and I shall be well content to be remembered, or even not remembered, as such."

How nobly he acted up to his principles we all know; how greatly the pursuit of his objects have benefited intellectual and material progress, we can only estimate.

In the preface of the fifth volume of his "Collected Essays," Huxley gives a quotation from Strauss's "Der alte und der neue Glaube," which describes so exactly the guiding principles of his life, that it is difficult to believe the lines were written by another hand nearly a quarter of a century ago. "For close upon forty years," wrote Strauss, "I have been writing with one purpose; from time to time I have fought for that which seemed to me the truth, perhaps still more, against that which I have thought error; and in this way I have reached, indeed overstepped, the threshold of old age. There every earnest man has to listen to the voice within: 'Give an account of thy stewardship, for thou mayest be no longer steward.' That I have been an unjust steward, my conscience does not bear witness. At times blundering, at times negligent, Heaven knows; but, on the whole, I have done that which I felt able and called upon to do; and I have done it without looking to the right or to the left; seeking no man's favour, fearing no man's disfavour."

Huxley leaves a wife and seven children—three sons and four daughters. They mourn the loss of a loving husband and father, and their affliction is shared by all who were fortunate enough to know him as a friend. But his loss will not only be felt by these; it affects the whole

intellectual world. Men will arise who, like him, will advance and extend scientific knowledge by research and exposition, but rarely will the qualities of the investigator and interpreter be combined with a more charming personality.

The funeral has been fixed to take place at Marylebone Cemetery this afternoon, at 2.30 o'clock.

NOTES.

AMONG the honours which Lord Rosebery recommended on leaving office, and which the Queen has approved, we notice that Dr. Robert Giffen, C.B., whose work in various departments of statistical science will be known to our readers, has become K.C.B., and that Prof. J. W. Judd has been appointed C.B. Mr. James Blyth, the well-known agriculturist, has received a baronetcy, Colonel V. D. Majendie, C.B., has been promoted to K.C.B., and Captain Lugard has been appointed C.B.

THE International Meteorological Committee, at its last meeting at Upsala, in August 1894, recommended that an International Conference of the same character as that of Munich in 1891, should be held at Paris about the middle of September, probably September 15, 1896. A circular has just been distributed among meteorologists, announcing that M. Mascart has undertaken to make the arrangements necessary for the meetings of the conference. Mr. R. H. Scott will be glad to receive, at the Meteorological Office, notes on any questions suitable for insertion in the programme for the conference. It is proposed that the definitive programme shall be prepared before the end of the present year 1895, in order to give meteorologists interested in the subjects proposed for discussion, time to formulate their views thereon.

THE death is announced of Prof. D. Kirkwood, for many years Professor of Mathematics in Indiana State University, and known for his investigations of the orbits of planets and comets.

AN influential committee has been formed in Paris, to collect funds for the erection of a monument to Francis Garnier, the explorer. The Treasurer of the Committee is M. J. Rueff, 43 rue Taitbout, Paris.

PROF. FUCHS has been elected a Correspondant of the Paris Academy of Sciences, in the Section of Geometry; Dr. Nansen has been elected a Correspondant of the Section of Geography and Navigation, and Dr. Laveran a Correspondant of the Section of Medicine and Surgery.

PROF. WILD has formally announced the resignation of his office at St. Petersburg as from September 13. His future residence will be at Zurich, and he requests that papers and books hitherto addressed to him at St. Petersburg, should be sent to his new address.

THE subject of the essays for the Howard Medal of the Royal Statistical Society, to be awarded in 1896, with £20 as heretofore, is "School Hygiene, in its Mental, Moral, and Physical Aspects." Essays should be sent in on or before June 30, 1896.

PROF. C. LLOYD MORGAN has accepted an invitation to deliver four lectures in the Columbia University Biological Course next winter. His subject will be "Some Habits and Instincts of Birds." Mr. Frank M. Chapman, of the American Museum of Natural History, will also give four lectures upon birds, from the zoologist's standpoint.

THE American Museum Expedition of 1895 has already completed the exploration of the Uinta basin fossil fauna, and established the fact that, like the *Phosphorites* of France, it is completely transitional between the Eocene and Miocene. The party is now passing north to explore Brown's Park on the eastern base of the Uinta Mountains, an ancient lake basin which has been long known but hitherto unexplored for fossils.

THE Executive of the Midland Union of Naturalists at their annual meeting, held on Monday last at Oxford, awarded to Mr. Walter E. Collinge, Assistant-Lecturer in Zoology and Comparative Anatomy, Mason College, Birmingham, the "Darwin Medal" for his recent researches on the cranial nerves and sensory canal system of fishes.

MR. GEORGE S. DAVIS, who, since January 1885, has at a very heavy loss maintained the "Index Medicus," announces he will be obliged to discontinue that very useful publication, owing to insufficient support. It would hardly be to the credit of medical societies, and scientific workers generally, if this indispensable monthly index is allowed to come to an end for want of something like £400 a year.

THE fortieth annual exhibition of the Royal Photographic Society will be inaugurated on Saturday, September 28, by a private view, followed in the evening by a conversazione. The exhibition will remain open daily (Sundays excepted) from September 30 until November 14. Medals will be placed at the disposal of judges for the artistic, scientific, and technical excellence of photographs, lantern slides, and transparencies, and for apparatus. The judges for the technical section are Captain W. de W. Abney, Mr. Chapman Jones, and Mr. Andrew Pringle.

AN International Exhibition of Hygiene, organised under the direction of M. Brouardel, was opened at Paris on Thursday last. The exhibits are divided into five groups, referring respectively to (1) the hygiene of private houses; (2) city hygiene; (3) the prophylactics of zymotic diseases, demography, sanitary statistics, &c.; (4) the hygiene of childhood, including alimentary hygiene, questions of clothing, and physical exercises; (5) industrial and professional hygiene.

THE *Weekly Weather Report* of the 29th ult. shows that the rainfall for the first half of this year is much below the average in all districts except the north-east of England. The deficiency varies from 2·5 inches in the east of Scotland, to 5 inches in the south-west of England, but in the west of Scotland the deficiency amounts to 12 inches. Some heavy amounts have, however, been measured recently; at Churchstoke, Montgomery, the abnormally large fall of 4·83 inches was recorded on the 26th ult.

A FEW days ago, the Lord Mayor of Liverpool, on behalf of the Museum Committee of the Corporation (of which Sir William B. Forwood is chairman), opened in the Public Museum, in presence of a numerous assembly, a large new gallery exclusively devoted to ethnography. An interesting account of the origin and history of the collection, and of the method of its arrangement, was given by Dr. H. O. Forbes, the Director of Museums. The African, Papuan, and New Zealand sections are especially rich, while those of Mexico, Peru, and Patagonia contain some very rare exhibits of exceptional value.

AT the annual general meeting of the Society of Arts, the following gentlemen were elected Vice-Presidents:—Sir Edward Birkbeck, Mr. B. Francis Cobb, the Hon Sir Charles W. Fremantle, Sir Douglas Galton, and Prof. W. C. Roberts-Austen. To fill the places vacated by retiring members of Council, there were elected, at the same meeting, Sir Steuart Colvin Bayley, Major-General Sir Owen Tudor Burne, Mr. R. Brudenell Carter, and Dr. Francis Elgar. Sir Frederick Bramwell was elected Treasurer of the Society.

The following recent appointments are announced in *Science*. To be assistant professors in Johns Hopkins University: Dr. C. Lane Poor, astronomy; Dr. A. S. Chessin, mathematics and mechanics; Dr. Simon Flexner, pathology: Dr. Albert Mann to be professor of biology in Ohio Wesleyan University. In Syracuse University, Dr. E. C. Quereau to be professor of geology and mineralogy, and Dr. W. H. Metzler associate professor of mathematics. Mr. M. A. Mackenzie has been appointed professor of mathematics in Trinity University, Toronto. The chair of physics in the University of California, recently filled by the late Prof. Harold Whiting, has been offered to Dr. E. P. Lewis.

A novel engineering scheme in the construction of the foundation of the retaining wall of the new speedway at High Bridge, in New York City, is the freezing of a bed of quicksand which impeded the work. A row of 4-inch pipes have been sunk a few feet apart, to the depth of 40 feet. These pipes are capped at the bottom, and inside them are inserted smaller pipes, open at the bottom. Cold air is forced from a condenser through the smaller pipes into the larger, and thence returned to the condenser. The air is cooled by expansion to a temperature of about − 45 C., thus freezing the surrounding mud and wet sand, and checking the flow into the excavation.

Those who have read Prof. Crum Brown's "Robert Boyle" Lecture, reported in our columns (vol. lii. p. 184), will be interested to learn that among the "Studies from the Princeton Laboratory," contributed to the current number of the *Psychological Review*, there is a paper on "Sensations of Rotation," by Mr. H. C. Warren. The particular object of this investigation was to determine the relative influence of sight and the internal sense of rotation on the subjective estimate of movement. By means of a mirror—which could be inserted or removed at will—the apparent motion, as given to sight, could be reversed. For the detailed results the paper itself must be consulted. In general they seem, we are told, to favour the view that the semicircular canals constitute the organ for the sense of rotation.

The Meteorological Office has received from the Central Physical Observatory of St. Petersburg, copies of a circular addressed to various institutions with reference to a proposed meteorological exhibit at Nizhny-Novgorod Exhibition in 1896. The Central Physical Observatory being desirous of making this exhibit as complete as possible, and at the same time of making known to the Russian public the progress of meteorological science in various countries, desires to obtain information on any of the following points: (1) Number of stations, of different orders. (2) Titles of periodical publications, any of which will be exhibited. (3) Summary of practical applications of meteorology, with titles of any works on the subject. (4) Copies of works containing mean values or references to them, instructions for taking observations, descriptions of instruments with methods of exposure, and charts referring to maritime meteorology.

The autumn meeting of the Iron and Steel Institute will be held at Birmingham from Tuesday to Friday, August 20-23. The programme will embrace visits to the leading industrial establishments in and around Birmingham. The Mayor of Birmingham will hold a reception, at the City Council House and Art Gallery, on the evening of August 20. The Earl and Countess of Warwick will also give a reception at Warwick Castle. Among the papers that are expected to be read are:—"The Thermo-chemistry of the Bessemer Process," by Prof. W. N. Hartley, F.R.S.; "The Hardening of Steel," by H. M. Howe; "The Mineral Resources of South Staffordshire," by H. W. Hughes; "On Tests of Cast Iron," by W. J. Keep and by T. D. West; "The Estimation of Oxide of Iron in Steel," by A. E. Tucker; "The Use of Nickel in the Metallurgy of Iron," by H. A. Wiggin.

Prof. Kikuchi, of the Science College, Tōkyō, is preparing a short life of the late Prof. Cayley, to be accompanied by a photograph, for a Japanese popular scientific monthly, viz. the "Tōyō Gakugu Zasshi."

A remarkable system of electric lights on buoys has just been completed at the Gedney Channel, off Sandy Hook. This channel is only 1000 feet wide, and vessels have not heretofore been able to pass through it by night. The new system, however, provides a brilliant thoroughfare, lighted by ten incandescent lights of 100 candle-power each, and each on a buoy, about 50 feet long, and rising 12 feet out of water. The cable which conveys the electricity carries the pressure of 1000 volts under water, and is six and half miles long, being the longest cable in the world carrying a high-pressure current under water, and also the only one of its kind ever made. It consists of a copper conductor, insulated with gutta-percha, bedded in jute, and sheathed with hard drawn copper wire. The machines have an output of only 100 volts, but the current flows through a step-up converter, back of the switchboard, where it is converted into the required voltage, thus being perfectly safe to operate.

The palæontological department of the American Museum has recently secured by purchase the entire collection of fossil mammals of North America brought together by Prof. E. D. Cope since 1870. This includes 552 of Prof. Cope's mammalian types, besides the unique single skeletons of Phenacodus, Hyracotherium and Hyrachyas, and the rich series from all formations described and figured in Cope's Tertiary Vertebrata, besides all his unpublished material. This famous collection, together with the others which are rapidly coming in from the annual western expeditions to the Rocky Mountain region, will be arranged in the large new hall upon the geological floor of the Museum, which has been designed and cased for the purpose. The collections are being prepared for exhibition and research as rapidly as possible.

By the kindness of Mr. R. H. Scott, we are able to print the following information received at the Meteorological Office with reference to some recent earthquake disturbances in the Leeward Islands. The note was drawn up by Mr. F. Watts, the Government Analytical Chemist at Antigua, and was sent to the Colonial Office with two letters on the effects of the earthquake in Barbuda. "On Monday, May 20, 1895, a long and somewhat severe earthquake shock was felt in Antigua at 4.44 p.m. This shock threw down a steel rod 4 inches long and $\frac{1}{8}$ inch in diameter, in a rough earthquake indicator at Skerretts. Slight shocks followed at intervals. I was able to ascertain that there were at least seven shocks between 4.44 and 8.20 p.m. A shock at 6.58 p.m. was rather severe, causing one of the Cathedral bells to sound slightly and stopping the clock. Slight shocks have been experienced almost every day since. Similar shocks are reported from Montserrat, Nevis, St. Kitts, and Barbuda. Some injury to buildings is reported from Barbuda, but I am unaware of the extent of the damage. It is stated that distant sounds, as of explosions, were heard in Barbuda; these appear to have been heard in a northerly direction. Through the courtesy of the Telegraph Company, I am informed that these earthquakes have not been felt in any islands save those in the groups Antigua, Montserrat, Nevis, St. Kitts, Barbuda. From this fact, coupled with the report of noises heard in Barbuda, I should infer that these disturbances are purely local, and in no way related to the earthquakes in Europe about the same time."

An elaborate investigation on the bacterial contents of margarine and margarine-products has been recently made by Messrs. Jolles and Winkler. It is satisfactory to find, in view of the large quantities of margarine which are placed on the

market in one form or another, that it is considerably freer from microbes than ordinary butter when the latter is not made with Pasteurised cream. Whereas butter contains an average of from 10 to 20 millions of microbes per grm., margarine-butter yields but from 4 to 6 millions; moreover, whilst in extreme cases as many as 47 millions of microbes have been found per grm. in butter, margarine can only boast of at most something over 11 millions. Cold appears to act more prejudicially on margarine microbes than it does on butter germs; thus in one case a reduction from $6\frac{1}{2}$ millions to 230,200 per grm. was observed in margarine, whilst a similar exposure never succeeds in eliminating more than one-third of those present in butter, according to Lafar. It is reassuring to learn that in none of the numerous samples examined were pathogenic bacteria discovered; many of the ordinary microbes present were isolated and described, and amongst these two were found which the authors believe are closely associated with rancid processes which occur in old samples of margarine. To further reduce the microbial population of margarine butter, it is suggested that only sterile milk and sterile water should be used in its manufacture from oleo-margarine, which is considerably poorer in bacterial life than the finished product.

IN the years 1891 and 1892, the Norwegian Government fitted out a vessel for the purpose of making temperature observations round the Lofoden Islands, with the view of tracing the connection between the habits of the cod and the temperature of the water, and the Parliament voted a sum of money for the purchase of thermometers for registering the temperature at various depths. We have received from Lieutenant G. Gade, who was entrusted with the investigation, a pamphlet entitled "Temperaturmaalinger i Lofoten," which contains an interesting account of the results obtained. He found that at the same places the temperature sometimes increased regularly according to the depth, while at others there were two distinct strata of water, the cold being uppermost. Although the vertical variations of temperature may have been considerable, yet he always found an increase with depth. The favourite temperature of the cod is supposed to be 5° C., and while in January 1892 this was found at the surface, in March 1891 it was only found at a depth of 160 metres; the greatest depth at which fishing takes place is 200 metres, where 6°–7° C. were recorded nearly constantly from January to the middle of April. Lieutenant Gade found that when there were two strata of water, one cold (2°–3° C.) uppermost, and one warmer (5°–7° C.) below, the cod was always found in the warmer stratum; but, as the fishing takes place at depths where the temperature is from 4°–7° C. or more (and the depths where these temperatures are found are very different), the author considers that the fisherman cannot derive practical advantage from temperature observations alone.

CHORISIS, or the doubling of the parts, is by no means a rare occurrence in flowers. In this phenomenon there appear, apparently in the place of one floral leaf, especially a stamen, two such leaves either collaterally, *i.e.* beside one another, or serially, above one another. These pairs of leaves may arise either out of a single common primordium, or directly from the axis. Up to the publication of a paper on "Das Reductionsgesetz der Blüthen," by Dr. Lad. J. Čelakovský (Stzb. der königl. böhmischen Ges. der Wissenschaften), morphologists agreed in regarding chorisis as the division or branching of an originally simple leaf. Dr. Čelakovský, however, comes to the following conclusions, amongst others, after a very complete consideration of a large number of instances. Normal chorisis occurs not as a division of a single leaf, but rather as a fusion, or at least an approximation of distinct and originally uniformly separated leaves. In the ontogeny of the plant this may occur as a branching or positive chorisis, as he terms it, of a single primordium, but this fact does not afford, according to him, a clue to the steps in the phylogenetic development, by which the present state has come about; but he believes, in opposition to the hitherto received opinion, that the present condition in these flowers was attained by negative chorisis or approximation. Normal chorisis is the expression of an incomplete transition from a state in which the individual leaves composing a whorl or whorls were more numerous, into one in which they are less numerous. It is, in fact, the resultant of two tendencies—one, the older, to polymerism, and the other and newer, to oligomerism. The reduction so effected is always governed by the law of the alternation of the consecutive leaf-whorls. Dr. Čelakovský's paper is one of great interest, and the discussion as to the origin of the various types of andrœcium will no doubt be specially useful to those who are interested in the affinities of the natural orders of dicotyledons and monocotyledons.

THE publishers of *Knowledge* announce that Dr. Isaac Roberts, F.R.S., will shortly continue in that magazine his selection of photographs of stars, star-clusters, and nebulæ. The series is intended to be in continuation of Dr. Roberts's work, "A Selection of Photographs of Stars, Star-Clusters, and Nebulæ," recently published, and which has contributed very largely to the extension of the knowledge of astronomical phenomena.

THE July number of *Natural Science* is devoted to brief descriptions of the results of the *Challenger* Expedition, from the points of view of investigations in many branches of knowledge. Each of the contributors, all of whom write with authority upon their respective subjects, more or less confines himself to answering the question, "How has the *Challenger* Expedition advanced science?" The brief summaries thus obtained form a very valuable and compact index to the advances in various fields of natural knowledge due to the Expedition.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Mr. John Norbury, Junr.; a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Mr. H. W. Ball; a Black-eared Marmoset (*Hapale pencillata*) from South-east Brazil, presented by Mr. H. P. Roberts; a Rough Fox (*Canis rudis*) from British Guiana, presented by Dr. Irvine K. Reid; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Lady Champion de Crespigny; seven Black Salamanders (*Salamandra atra*), a Slowworm (*Anguis fragilis*) from Switzerland, presented by the Rev J. W. Horsley; a Burchell's Zebra (*Equus burchelli*, ♂) from South Africa, a Common Rhea (*Rhea americana*) from South America, deposited; two Black-necked Swans (*Cygnus nigricollis*) from Antarctic America, three Blue Snow Geese (*Chen cærulescens*) from Alaska, purchased; a Thar (*Capra jemlaica*, ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

VARIABLE STARS.—Dr. Chandler has completed a revised supplement to his well-known second catalogue of variable stars; together they furnish a complete list of known variables, comprising in all 344 stars. Some little difficulty has been experienced in connection with the southern variables, on account of the want of accurate positions and certain identifications in some cases. Dr. Chandler especially shows a want of confidence in the data relating to the variables discovered photographically at the Boyden station of the Harvard College Observatory at Arequipa, ; but considering the pressing need of a definitive nomenclature, and relying on the assurances of Prof. Pickering, most of these objects have been included in the catalogue and letters assigned to them.

All the recent observations made by the South African ob-

server, Mr. Roberts, have also been included in the new catalogue. (*Astronomical Journal*, No. 347.)

The Temperature of the Sun.—A new method of determining the temperature of the sun has been employed by H. Ebert (*Astrophysical Journal*, June). With the aid of data supplied by Langley's investigations, Rubens deduced the law that the wave-length of the maximum energy is inversely proportional to the square root of the absolute temperature of the radiating body. Experiments on the radiation of blackened bodies between absolute temperatures 373° and 1088° indicated the relation

$$\lambda\sqrt{T} = 123,$$

T being the absolute temperature, and λ being expressed in microns ($\mu = \cdot 001$ mm.). Langley has shown that the maximum energy of the continuous background of the solar spectrum is very nearly at 0·6 μ, and assuming that the incandescent particles in the sun which yield the continuous spectrum are comparable to a black body as regards their total radiating capacity, the application of the above formula gives a temperature of about 40,000° C. The parts of the sun to which this temperature applies are stated to belong to the interior regions, below the photosphere.

Dr. Ebert enters into a discussion of the electromagnetic nature of the solar radiation, in order to justify the application of the formula in the case of the sun. This leads him incidentally to suppose that the continuous background of the solar spectrum is mainly due to hydrogen in a strongly compressed state.

The Rotation of Saturn.—In 1893 Mr. Stanley Williams announced some highly interesting facts with reference to the period of rotation of Saturn, as deduced from observations of spots on different parts of the surface of the planet (Nature, vol. l. p. 32). The observations were continued during the opposition of 1894, and similar striking results have been arrived at. (*Monthly Notices*, vol. lv. p. 354). It was again found that the spots indicated widely different rotation periods in the same latitude, but in different longitudes, as shown in the following table:—

	Range in longitude.	Mean period. h.	m.	s.
Dark spots (17°–37° N.)	30–130 … … .	10	14	57·29
	140–200 … …		14	44·23
	240–360 … . ..		15	47·97
Bright spots (6° S.–6° N.)	0–80 … … . .		13	1·69
	80–160 … …		12	40·03
	160–360 … … .	10	12	25·83

The average rotation periods of the whole equatorial spot zone during the four years of observation were as follows:—

	h.	m.	s.		s.
1891 . . …	10	14	21·8	Diff.	43·6
1892 ..		13	38·2	,,	45·8
1893 .. …		12	52·4	,,	16·6
1894 … ..	10	12	35·8		

The extreme difference of 1m. 46s. observed since 1891 "means a very considerable increase in the velocity of motion of the surface material, amounting to 66 miles per hour. In other words, the great equatorial atmospheric current of Saturn was flowing 66 miles an hour more quickly in 1894 than it was in 1891."

Taken as a whole, the observations indicate a more rapid rotation of the planet in the equatorial regions than in the northern zone of spots, and they appear to establish that there are great differences of velocity in different longitudes.

To Prof. Darwin, these results "suggest a rather wild consideration" (*Observatory*, June). He considers it possible that sections of the planet parallel to the equator may not be circular, and suggests that it might be worth trying to detect systematic differences between the various equatorial diameters by micrometric measurements.

THE VISIBILITY OF SHIPS' LIGHTS.

It may be remembered that in 1890, the German Marine Observatory tested some three thousand running lights in use on board ships, and found two-thirds of them defective. Further tests of the visibility of lights of known candle-power were made by the German Committee last year, and some of the results obtained are noted in a leaflet just distributed to seamen by the U.S. Weather Bureau. The law of emission for a white light is that its visibility is proportional to the square root of its candle-power, and the results of the experiments by the Committee closely follow the law, the departures being no greater than the estimated errors of position of the vessel. The mean of a large number of observations gave as the distance at which a white light of one candle-power became visible 1·40 miles for a dark clear night, and 1·00 mile for a rainy one. Experiments undertaken in America, after the International Maritime Congress in 1889, gave the following results in very clear weather: A light of 1 candle-power was plainly visible at 1 nautical mile, and one of 3 candle-power at 2 miles. A 10 candle-power light was visible with an ordinary binocular at 4 miles; one of 29 candles faintly at 5, and one of 33 candles visible without difficulty at the same distance. On a second evening, exceptionally clear, a white light of 3·2 candle-power could readily be distinguished at 3, one of 5·6 at 4, and one of 17·2 at 5 miles. The Dutch governmental experiments, conducted at Amsterdam, gave the following results: A light of 1 candle-power was visible at 1 nautical mile; 3·5 at 2, and 16 at 5 miles. Experiments with green lights gave 0·80 as the distance in miles at which a green light of a single candle-power is just visible. The candle-power required for a green light to be visible at 1, 2, 3, and 4 nautical miles was 2, 15, 51, and 106, respectively. The American experiments before referred to give for green light: 3·2 candle-power fairly visible at 1 mile, and 28·5 clearly at 2 miles, these results being, however, from a limited number of experiments. The German trials were much more numerous. The extraordinarily rapid diminution of the visibility of the green light with the distance, even in good observing weather, and the still more rapid decrease in rainy weather of a character which will but slightly diminish the intensity of a white light, show that it is of the utmost importance to select for the glass a shade of colour which will interfere with the intensity of the light as little as possible. The shade recommended is a clear blue-green. Yellow-green and grass-green should not be employed, as they become indistinguishable from white at a very short distance. For the red, a considerably wider range is allowable, but a coppery-red is said to be the best.

THE RELATIVE POWERS OF LARGE AND SMALL TELESCOPES IN SHOWING PLANETARY DETAIL.

It is to be hoped that a definite understanding will soon be arrived at regarding the differences between large and small telescopes in revealing delicate surface-markings on Mars, Jupiter, and Saturn. The subject of relative efficiency was discussed about ten years ago, and some interesting evidence was evoked as to the different forms and sizes of telescopes, but no settlement of the question was possible in the face of the diversity of opinion existing. The time seems to have come when the subject may be suitably referred to, and the facts considered apart from mere prejudice or preference for any kind or size of instrument.

The phenomenal results recently claimed for certain small telescopes are almost of a character to shake even the faith of those disposed to acknowledge their great utility on several classes of objects, for our confidence cannot go beyond reasonable limits. In individual cases a good though small instrument, an acute well-trained eye, acting in combination with the best atmospheric conditions, will yield surprising results; but some of those lately published border upon romance, and henceforth it would seem that if all the data derived with such means are to be absolutely accepted, then large telescopes are grossly incapable on certain important objects, and may as well be packed away in the lumber rooms of our observatories.

This is the more surprising when we consider the opinions expressed during the discussion which previously took place on the same subject. Prof. C. A. Young, who has charge of the 23-inch refractor at Princeton, said: "I can almost always see with the 23-inch everything I see with the 9½-inch under the same atmospheric conditions, and see it better—if the seeing is bad only a little better, if good immensely better." Other observers having the means of comparing large and small instruments, side by side, furnished similar evidence, except in the case of M. Wolf, of Paris, who said: "I have observed a great deal with two instruments (both reflectors) of 15·7 and 47·2 inches aperture. I have rarely found any advantage in using the larger one when the object was sufficiently luminous." Prof. Asaph Hall, whose

valuable work with the 25·8-inch refractor at Washington is so well known, once said: "The large telescope does not show enough detail." The testimony was not, therefore, unanimously in favour of big telescopes.

More recently the 36-inch at Mount Hamilton has been eulogised for its fine performance. Mr. Keeler, in January 1888, said that the minutest details of Saturn's surface were visible with wonderful distinctness with this instrument. The 12-inch and 6-inch refractors at the same observatory were found far inferior in capacity to the 36-inch. Prof. Barnard has also stated: "Let the conditions be the best for observing, with the air steady, and the 36-inch is far ahead of the 12-inch." The same observer has also remarked: "350 is the most useful power on Jupiter and Mars, 520 on Saturn." For planetary work he prefers using the full aperture and low powers.

We have it on the authority of most of those who have employed both large and small telescopes, and are therefore in the best position to speak as to their relative merits, that large instruments in good air will reveal more than small ones. The observer would in preference use the largest instrument for any critical purpose: and this being so, how shall we explain their apparent failure in regard to planetary details? Is it that the big telescopes show too little, or that the small instruments exhibit too much?

And here it may be noted that only in exceptional cases do we find phenomenal results accruing from the use of small apertures. It is not every one who has a telescope of 6 or 8 inches diameter who can discover the various spots and numerous belts on Saturn, or trace the double and often interlacing canals of Mars.

During the last few years numerous dark and light spots have been detected on the ball of Saturn by Mr. A. S. Williams, who used a 6-inch reflector. These have been distinguished when Saturn was nearing conjunction with the sun, and in spite of two unfavourable circumstances—namely, the small diameter of the planet, and its proximity to the horizon. The spots have been seen so distinctly, that the observer has been enabled to describe them individually as bright or faint, small or large, round or oval, &c. These observations have not, perhaps, been fully corroborated, though several observers appear to have glimpsed the markings alluded to. When we consider that many hundreds of amateurs have been employing their telescopes upon Saturn without seeing the spots, the affirmative evidence of a few isolated persons can hardly be regarded as conclusive. It is a fact that, if any new feature on a planet, or an unknown companion to a star were confidently announced, a few of the many observers who looked for it would certainly assert they could see it though not really existing.

Prof. Hough, with the 18½-inch refractor, at Chicago, made a series of observations in 1884 and 1885 for the special purpose of detecting definite markings on Saturn and redetermining the rotation period, but he quite failed to get the necessary data. His statement was: "The belts on the disc of the planet were at times quite conspicuous and very sharply defined, but we were unable to find any spot or marking by which to observe rotation." Yet the *Monthly Notices* for June 1884 contain a drawing which gives a numerous array of condensations attached to the dark narrow belt bounding the equator on its southern side. This drawing was made with an 8¼-inch reflector, and at about the same period many other observers examined the planet with an entirely negative result as far as the existence of these condensations was concerned. A drawing was published in the *Journal* of the British Astronomical Association for July 1894, showing the planet as he appeared on March 26 of that year in a 12-inch reflector. A numerous assemblage of dark belts are shown, and many other observers appear to have seen several comparatively narrow belts. Prof. Barnard, however, using the 36-inch refractor in re-measuring the dimensions of Saturn and his rings in 1894, was led to pay some attention to the physical appearance of the planet, and significantly remarks: "But one dark narrow belt was seen upon the planet. The black and white spots recently reported with small telescopes were not seen at any time." It is certainly a remarkable circumstance that the belts and spots, if really existing, cannot be seen in the large instrument. Are the observers with small apertures suffering from some extraordinary hallucination, or must we consider that the brightness of the image in large telescopes and inferior definition are sufficient to obliterate very delicate markings? Is the glare sufficiently strong to overcome the slight contrasts of tone readily perceptible on a fainter image? Prof. Holden thus expressed himself in 1891: "There is no doubt that the belts on Saturn are often marked and mottled with brighter spots. I presume that such spots would be as easily seen in a small but perfect telescope as in a larger one. Seeing such faint markings is entirely a matter of detecting faint contrasts, and these should be detected as readily in a small instrument as in ours, if not more readily, except that the large size of our image helps us." On the other hand, Prof. Young has suggested that faint images are very encouraging to the imagination, and therefore often a source of observational errors.

Prof. Holden's remarks are tantamount to an admission that large instruments are ineffective on planetary details, for what are delicate markings but "faint contrasts"? Yet it would be conceived that the 36-inch had proved itself quite capable of dealing with such contrasts, for it is stated by Prof. Barnard, from observations of Jupiter in September-October 1894: "The red spot is fairly distinct in outline, though quite pale—a feeble red. The following end of the spot is quite dark. There are white regions on its surface. The belt south of it seems to be in contact with the spot, if it does not actually overlap it slightly."

The 36-inch is mounted in one of the finest localities for celestial observations, but shows nothing on Saturn but the dark narrow belt situated in the midst of the equatorial zone, while certain telescopes of small aperture reveal the disc furrowed with belts and mottled with spots. Nearly every small telescope shows more than one belt upon Saturn, but the delineations seldom agree as to the number or latitudes of these belts. We ought to expect approximately accordant positions; but the majority of drawings are hurriedly executed and based on rough estimations, so that they are often found inconsistent. The differences referred to are not, therefore, proof of the non-existence of the objects depicted, for the same disagreements are found with reference to well-assured formations. In some cases undoubtedly observers will, perhaps unconsciously, use their imaginations, as the desire is always to put in as much detail as possible. When mere fancy assists the optical powers, the resulting drawings are often very pretty and attractive from the number and novelty of the features shown. We can fill in any number of dark belts and bright zones, beaded with spots of various forms and tints, and tone the whole to suit our ideas; but unfortunately such drawings, though pleasing to the eye, have a bad influence, since they pervert the truth, and lack that fidelity to nature which could, alone, make them really valuable.

Mr. Williams, the discoverer of the Saturnian spots, has made some hundreds of observations of them, and fully detailed his methods and his results in the *Monthly Notices* of the R.A.S., liv. p. 297, *et seq.* First detecting them in the spring of 1891, he has now followed them during five oppositions of Saturn. The bright equatorial spots apparently show a period of rotation decreasing with the time, for the mean period during 1891 was 10h. 14m. 22s., while in 1892 it decreased 44 seconds, in 1893 43 seconds, and in 1894 15 seconds. The care with which Mr. Williams proceeded in his work, and the plan he adopted to avoid bias or preconceived ideas, are explained in the paper alluded to, and every one reading his description must be favourably impressed with it. *If his results are fully confirmed*, they will deserve to be ranked among the best observational feats of modern times. To have been the first to discover these delicate objects in all their variety, to have traced out their individual motions with unwearying persistency year by year, and to have employed all the time a very small telescope, must be regarded as a remarkable attainment. It is to be hoped that the necessary corroboration will soon be forthcoming.

I have myself practically endeavoured to afford this, but failed. The spots on Saturn are certainly not visible under powers of 252 and 312 on my 10-inch reflector. The power of 252 is the eye-lens of a Huyghenian eyepiece, that of 312 is one of the "monocentric micrometer oculars" of ¼-inch equivalent focus by Steinheil of Munich. The latter has a distinct advantage over my Huyghenian eyepieces. I have sometimes used a Barlow lens in combination with it, increasing the power to about 450, but do not think any advantage has been gained. I have occasionally had impressions of white spots mottling the bright equatorial zone of Saturn, and occasionally also of faint condensations in the dark belts; but as to seeing these details outright, and obtaining their times of transit with all the certainty of a definite spot on Jupiter, I have quite failed. I am induced to believe, from a number of observations dedicated to

the purpose, that my suspicions of spots were entirely illusory, and that such markings as objective features were invisible to my eye with the means employed. On the worst nights I could easily imagine a mottled aspect of the belts; but with good definition and a steady image, the tone of the belts and bright equator appeared perfectly even and free from noticeable irregularities. In a case of this kind the observer has to be severe with himself. There is a distinct line of demarcation between what is absolutely seen and what is possibly seen or suspected. An object may be only glimpsed, and yet it is certainly seen, for its impressions reach the eye now and then in a form not to be mistaken. But with some objects the experience is different. We fancy they are there, but cannot fix them with certainty; apparently they flit about like an *ignis fatuus*, and are intractable to our utmost efforts. Obviously in such a case the observer has but one alternative, and that is to regard the objects as imaginary.

On Mars, as well as Saturn, small instruments have done wonders. It is well known that the canals and their duplication were discovered by Schiaparelli with a refractor of only 8¼ inches aperture. In 1892, during a favourable presentation of Mars, the large American telescopes showed very little either of the canals or of their duplication. During the opposition of 1894 the planet was better placed as regards altitude (but not so near to the earth as in 1892), and the results of observations have been more satisfactory. Mr. Williams with a 6½-inch reflector, and Mr. Brenner with a 7-inch refractor, have recovered many of the double canals of Schiaparelli. Mr. P. Lowell, with the 18-inch refractor at the observatory at Arizona, has also observed many remarkable and intricate details of the planet's topography. This observer remarks that in regard to the visible markings on the inner planets of the solar system up to and including Mars, size of instrument is quite secondary to quality of atmosphere. He draws the "oases" on Mars, and a large number of interlacing lines on the planet, in *Popular Astronomy* for April 1895, and the pictures are very effective. There are many of us who would like to obtain a view of Mars similar to what he has depicted. Mr. Lowell notes that with the 18-inch a power of 420 was as high as the atmosphere permitted to be used with advantage, though drawings were generally made with 370. On the 6-inch refractor 270 showed well, the dark and light markings being more contrasted than in the larger instrument. As affecting the comparative utility of large and small telescopes, Mr. Lowell remarks: "A large instrument is assumed to be necessarily superior to a small one, quite irrespective of what it is that is to be observed. Now the fact is that there are two quite different classes of celestial phenomena—those dependent on quantity of light, and those dependent on quality of definition for their visibility, and the two means to these ends go anything but hand in hand. For the one, the illumination, the size of the instrument is the prime requisite; for the other, the definition, the atmosphere is the first essential. As an object-lesson in this, it is worth noticing that the biggest instruments have not always given the best views of Mars. In matters of Martian detail it is amply evident from the results that observer, atmosphere, instrument, is the order of weight to be given as the factors of an observation."

I have referred to this subject without any desire to take up the cudgels on behalf of any class of instrument, but it is suggestive that the large ones will not bear powers commensurate with their size on planetary details. Thus with the 36-inch at Mount Hamilton a power of 350 has been found the most effective on Mars: a similar power can be used with advantage on glasses of only 8 or 10 inches diameter. It is difficult to understand, therefore, where the superiority of large instruments comes in, as the object is sufficiently bright in small telescopes, and the latter being more easily manipulated and less affected by atmospheric tremors, they obviously possess some distinct advantages. But this interesting and important question is scarcely to be settled by a mere discussion of this sort. It is only to be settled by careful trials of large and small instruments, side by side, upon the planets Mars, Jupiter, and Saturn. If observers having the appliances at command will institute some further comparisons of the kind suggested, the problem might be virtually solved in a short time. Relying upon evidence of fragmentary character is scarcely fair, as the differences of eyesight and atmosphere come into play most prominently. The most valuable evidence would be that of an observer who used a number of telescopes of different apertures at one and the same station. Up to the present time it must be confessed that small instruments have somewhat the best of the argument; but if the unanimous testimony of our most trustworthy observers asserted the superiority of large telescopes on bright planets, it is hard to see how they could be disproved, as they alone have the effective means of judging the question on its merits.

W. F. DENNING.

SUBJECTIVE VISUAL SENSATIONS.[1]

THE activity of the cerebral centres which is independent of their common exciting causes, and which is termed "discharge," presents indications of the character and loss of their function which can be obtained from no other source. Foremost in interest and also in importance are the sensations of sight which occur without stimulation of the retina. Of these the most important are two. (1) Those which occur at the onset of epileptic fits, from the "discharge" in the brain influencing consciousness, through the visual centre, before loss takes place. (2) Those which occur as the precursory symptoms of the paroxysmal headaches which, from their one-sided distribution, have been called "hemicrania," "megraine" or "megrim," from the frequent vomiting, "sick headaches," and, from the inhibitory loss of sight, "blind headaches." These two classes form the subject of the lecture.

In what part of the brain does the process occur? The impulses from the retina reach the cortex of the brain first in the extremity of the occipital lobe, where, as Munk first showed, the half-fields are represented in strictly local definiteness. The left occipital lobe receives the impulses from the left half of each retina, produced by the rays of light from the right half of each field of vision. So, conversely, with the right occipital lobe. To each side, impulses proceed from a very minute area around the central point of the retina, the fixation point of the field. But we cannot conceive that the functional disturbance occurs in these centres, for the strict medial division in two halves is absolutely ignored by the subjective sensations. Moreover, the strange but certain facts of hysterical hemianæsthesia, in which there is inhibition of all the sensory centres of one hemisphere, present us with remarkable evidence of the higher visual function in each hemisphere. This is supported by some cases of organic disease, which cause an affection of sight similar to that of hysteria, and by more common cases of hemianopia from disease of the hemisphere, in which there is a precisely similar contraction of the remaining half-fields. The significance of all these is that the early conclusions of Ferrier are correct, and that, in addition to the lower, occipital half-vision centre, there is a higher centre in each hemisphere, situated in the region of the angular convolution. This theory of the double visual centres, consisting of a combination of the conclusions of Ferrier and Munk, was first stated by the lecturer in 1885, and has been confirmed by all the facts he has since met with. It is indispensable for the comprehension of morbid functional action, and, indeed, for that of normal vision, but is not yet recognised by physiologists, even as hypothetical.

The character of the function of this centre, so far as it can be discerned from the facts of its loss, are of great importance for the study of visual sensations. The two higher centres seem to be blended into one in function in a manner that is unique so far as our knowledge extends. If the centre on one side is functionless, there is loss of sight in the periphery of both visual fields; there is vision in the central third of the eye on the same side, and a far smaller central area on the opposite side. The only conclusion is the startling inference that either higher centre can subserve central vision in both eyes, but that peripheral vision depends on the co-operation of the function of both hemispheres. Between the central area for which either centre suffices and the peripheral area for which neither is competent but both are needed, there is an intermediate zone in which vision is subserved only by the opposite hemisphere when acting alone. This gradation of functional capacity enables some facts of subjective sensations to be comprehended which cannot otherwise be understood.

Moreover, the facts suggest that the function of these higher centres is quite different from that of the lower ones, and from that of other cerebral centres the action of which we can study. In the lower half-vision centres function is localised, so that destruction of part causes absolute loss of a part of the half-field, blindness of the corresponding part of the retina. But partial

[1] The Bowman Lecture, delivered before the Ophthalmological Society, by Dr. W. R. Gowers, F.R.S., June 13.

damage to the higher centre seems to lower the function of the whole, as if the function were diffused, and all its elements were represented, in varying degrees, in every part. This conception is so unfamiliar that it may seem inconceivable, and yet it harmonises with many of the facts of subjective sensations. Moreover, in a large part of the brain, local loss of tissue has only the effect of lowering function as a whole. It seems to be only where the sensory impulses reach the cortex, and motor impulses leave it, that the local distribution of function is definite, and limited damage has definite and lasting results.

The spectra perceived before epileptic fits vary widely. They may be stars or sparks, spherical luminous bodies, or mere flashes of light, white or coloured, still or in movement. Often they are more elaborate, distinct visions of faces, persons, objects, places. They may be combined with sensations from the other special senses, as with hearing and smell. In one case a warning, constant for years, began with thumping in the chest ascending to the head, where it became a beating sound. Then two lights appeared, advancing nearer with a pulsating motion. Suddenly these disappeared and were replaced by the figure of an old woman in a red cloak, always the same, who offered the patient something that had the smell of Tonquin beans, and then he lost consciousness. Such warnings may be called psycho-visual sensations. The psychical element may be very strong, as in one woman whose fits were preceded by a sudden distinct vision of London in ruins, the river Thames emptied to receive the rubbish, and she the only survivor of the inhabitants.

The colours seen are chiefly described as red, green, blue and yellow. A yellowish red-like flame is very common. In some cases red changes to green, a curious complementary relation, when we consider that the sensation is due to a primary process in the centre. One obtrusive fact, in these spectra and in those of migraine, is the frequency with which colours extend to the edge of the field of vision. In one case, each fit was preceded by the appearance of a green colour occupying the lower half of the field so completely that the patient said he seemed to be in a field of grass. It is often said that the periphery of the retina is not sensitive to colour, and that red and green are seen only in the centre. But long ago, Chodin and Landolt showed that colour vision extends to the periphery. The peripheral colour spectra led the lecturer to make a careful examination of the peripheral colour vision, especially in regard to area, to which it seems to be related in a greater degree than to illumination.

Red can be seen up to the margin of the field for white, an area in 6 cm. square; green cannot well be discerned within 5° of the margin, but yellow and blue can be seen up to the margin with 4 cm. square. The fields for each area from ·25 to 4 cm. square are concentric with the field for white.

One fact was ascertained which illustrates the mutual influence of the two visual centres. When both eyes are open the two fields correspond, except in the outer temporal third of each field. The nasal half of left field, for instance, extends to 55° of the outer horizontal radius of the right field, the end of which is at 90°. When both eyes are open, not only is the perception of colour intensified in the part where the two fields overlap, but the intensification goes on to the periphery, through the part in which there is no more retinal stimulation than when the right eye alone is open. Thus, in this radius, red is seen in 2 cm. square at 62° with right eye alone, but at 74° if the left eye is also open, although the left field does not extend beyond 55°. The colour is seen in 4 cm. square at 77° with the right eye only, and at the margin of the field only with 6 cm. square, but with both eyes open the 4 cm. square enables the colour to be seen up to the margin, instead of at 77°. There is thus greater sensitiveness in the centres to colour impulses proceeding from the peripheral region, where the field is single, if light from the other eye intensifies their action—a striking instance of their intimate co-operation.

The motor relations of the epileptic spectrum are instructive but too complex for brief description. It is common, in one-sided fits, for an object to appear at the edge of the field of vision on the side afterwards convulsed, and pass across, to disappear at the opposite side. Its appearance, *e.g.*, on the left is followed by movement of the head towards it, by the motor centres of the right hemisphere, but the head then follows the movement of the spectrum, by the action of the centres of the other hemisphere (sometimes with a conscious sense of irresistible compulsion), and then finally deviates strongly in the first direction, as the convulsion comes on, usually with loss of consciousness. A sense of vertigo may accompany the deviation. The eyes move before the head, and may be absolutely fixed when the head can be moved by the will. These phenomena throw instructive light on the relations of objective and subjective vertigo. Inhibition frequently precedes the epileptic spectra, but is always general, never partial, and neither the loss nor the spectrum is ever on one side only. If they appear on one side, it is only to move across the field, apparently as the result of the effect on the visual discharge of the associated motor nature of the epileptic process.

The visual sensations which precede the paroxysmal headaches of migraine differ very much from the warnings of epilepsy. Their general character is limited, but their forms are extremely varied. One has been well made known by the careful study of his own sensations by Dr. Hubert Airey, published in the *Philosophical Transactions* for 1870, reproduced by Dr. Liveing in his classical work on megrim. (Unpublished drawings by Dr. Airey, and several other series of drawings were exhibited. One curious set was made by a mechanical draughtsman who, from sixty to sixty-five years of age, frequently experienced visual sensations, similar to those of migraine, as isolated symptoms, without headache, and always depicted them as objective things, related to his own figure.) In this class of spectra, inhibitory loss of sight is almost invariable, but it is always partial, never general as in epilepsy, and it bears a definite relation to the spectrum. The phenomena are generally on one side, but occasionally medial, although never central, and they never correspond to one half of the field.[1] Even loss strictly limited to the medial line, as in hemianopia due to organic disease, is practically unknown, contrary to the common impression. The special feature of the "discharge" is an angled line of light, the "zigzag" spectrum, single or repeated, sometimes in many, as it were reflected, fading, lines. In round or oval form it has been termed the "fortification spectrum," from resemblance to the plan of a fortress devised by Vauban. The angled line may be of simple bright light or may present colours, red, green, blue, orange, which sometimes alternate in successive segments. It often seems made up of a multitude of minute brilliant points in rapid movement. When a single bright line, it may be banded on each side by a very narrow black line. This feature may be observed in the "phosphene" produced by pressure on the eye, even in the dark, when it is apparently due to a limiting line of loss of the "essential light of the retina," but its presence in a central spectrum raises the question whether this so-called "light of the retina" is not of purely central origin.

The central region is remarkably indisposed to discharge, but prone to inhibition. A medical practitioner, a careful observer, experienced first a spot of central dimness of sight, which enlarged, becoming darker in the centre and ultimately extended from top to bottom of the field, occupying the middle third, banded on each side by a double curve. Sometimes, when the spot had reached half-way to the top and bottom of the field, a bright zigzag line appeared on one side, which extended upwards and downwards, as the inhibitory loss increased, became brighter, but seemed to restrain the inhibition, which extended no further on that side, but was, as it were, reflected back and reached almost the extreme edge of the field on the other side. This illustrates the occurrence of the discharge secondary to inhibition, and limiting it. It is an instance of the way in which all half-field relations are absent in these phenomena. The common commencement is for an angled sphere, or stellate spectrum, to appear in the middle zone of one half of the field, and, expanding, form an oval within which vision is partially or completely lost. The edge is often coloured. The angles are especially developed towards the outer side of the field. Towards the centre of the field the expansion is less, the angles smaller, and the spectrum breaks. Sometimes one limb passes downwards, and the other towards the central point, but in the latter the angles gradually cease, and the spectrum never reaches the centre—an illustration of the resistance of the central region to discharge. In other cases, however, the ends of the broken oval may pass into the other half of the field, one on each side of the central point, enclosing this between them. When they reach the middle zone on the other side, a second star, like that from which the spectrum originated, may suddenly appear for a short time as a terminal feature. These characteristics show how remarkable must be the relation of the centres in which their cause occurs.

[1] By "field" is meant the area included by the boundary of the conjoined fields of both eyes, to which alone the central phenomena seem related.

An angled spectrum of curved course may also develop by progression through the middle zone, beginning below, and attaining its chief development in the upper half of that side, passing only a little way beyond the middle line above. In one case this was preceded by a transient angled star near the point of commencement, and its early stage was accompanied by inhibitory loss at the margin of the field, outside the region in which the discharge commenced.

Although discharge never occurs at the central point, it may occur around it, as a circular zigzag, surrounding a round object looked at—an instructive example of the fact that the discharge may be related to the central effect of actual retinal stimulation. Analogous to this "pericentral" spectrum, is one that takes the form of an arch above the central region, which may separate into two parts at the middle line. As an instance of the strong tendency there is to regard the spectrum as an objective thing, a member of the medical profession, when asked to draw that which he saw, sent a drawing of his eye surmounted by an angled corona. These forms again indicate disturbance in centres in which there is no half-field representation. Besides other forms, an angled spectrum sometimes appears near the outer temporal edge of the field, and extends outwards for a short distance and then curves downwards, never upwards. Such a peripheral spectrum always seems to the subject to begin at the extreme edge of the field and extend outside it. In one case it was drawn as attached to the junction of the upper and lower eyelids.

It cannot be doubted that, by the study of these subjective symptoms, much will ultimately be learned regarding the function and mode of action of the cerebral visual centres. Whatever the drawbacks to observation through the consciousness of another person, knowledge can be gained in no other way of the action of the higher centres of the brain, and the time must come when the physiological knowledge which can be gained only through the effects of disease and the disturbance of functional derangement, will receive more attention. The facts of these spectra, when studied in their detail, compel the conclusion that they occur in centres in which function is related to the conjoint fields, and in these to a central and a peripheral region and to a medial zone between the two: that the chief relations are central and peripheral; that outside the central region there is a one-sided relation, but that there is no distribution of function at all corresponding to the division of the fields at the medial line. The dominant relation is concentric, and the indications afforded by the absolute one-sided loss caused by destruction of one occipital lobe, has no reflection, positive or negative, in these results of spontaneous central activity.

HIGH-LEVEL METEOROLOGICAL STATIONS.[1]

ONE of the greatest drawbacks to a full understanding of meteorological phenomena is that the observations on which we base our knowledge are generally made close to the ground in the most restricted air-stratum; whereas the general atmospheric movements, both in velocity and direction, are much modified in the lower strata, and the air surrounding and in contact with the earth differs greatly both in temperature and humidity from the free air. The more strongly agitated upper strata react on the lower in many ways, and a knowledge of the movement of the moderately high atmospheric layers is of great importance for the theory of the general circulation of the atmosphere, and practically for our weather forecasts, since the forces which develop storms have their origin and sphere of action within two or three miles of the earth.

If the atmosphere were only in complete equilibrium, then the few irregular observations, as regards time and place, which have been made in balloons, would give some data on which to base general laws; but, in the actual condition of continual movements and changes in the atmosphere, this can never suffice, and the continuous observations required of all the elements, at all seasons and in all weathers, can only be made on mountains, even though the conditions there only approximate to those of the free air. In this way observations on mountains complete those of the usual low-level stations.

When the earth's surface rises in plateaux, the advantage of elevation above the sea—that is to say, the immersion in the upper strata—is almost entirely neutralised, because still our instruments are placed in air masses which are affected by contact with the earth. For this reason meteorological observatories should be located on high and isolated peaks. The erection of such stations and the discussion of their observations during the last fifteen years have contributed largely to the rapid progress of the science of meteorology.

The chief first order stations (those possessing self-recording instruments, or where observations are made on an extensive scale) which are located on mountain tops in the various countries, will now be briefly described.

The first summit station in the world was that established in 1870, jointly by the U.S. Signal Service and Prof. J. H. Huntington, on Mount Washington, N.H., 6280 ft. above the sea. Probably nowhere else in the world has such severe weather been experienced, the lowest temperature being here often accompanied by the highest winds, unlike the calms which prevail with intense cold at low levels. For instance, in February 1886, with a temperature of 50 degrees below zero, a wind velocity of 184 miles an hour was recorded on Mount Washington. The Government meteorological station on Pike's Peak, at an elevation of 14,134 ft., was for many years the highest in the world. Now both these stations are closed, so that there seem to be actually in the United States but two summit stations where meteorological observations are made throughout the year, viz.: The Lick Observatory, on Mount Hamilton, California—primarily astronomical—and the Blue Hill Meteorological Observatory in Massachusetts, situated at a very moderate elevation. Prof. S. P. Langley's important researches on the nature and amount of solar heat received by the earth were carried on in 1881 upon Mount Whitney, the summit of which is 14,500 ft. above the sea.

It is due to an American institution that the highest meteorological station in the world is now in Peru, where the Harvard College Observatory, several years ago, established an outpost at Arequipa. In 1893, Prof. Bailey succeeded in placing self-recording instruments on the summit of the neighbouring volcano of El Misti, 19,300 ft. high, when a former station on the side of Mount Chachani, near the snow-line, at an elevation of 16,650 feet, was abandoned. It is impossible for persons to remain at these stations, so they were provided with automatic instruments which should give a continuous record of the chief meteorological elements during two weeks. Several times a month one of the Observatory staff climbs the mountain in order to wind the clocks and change the register sheets, at the same time making a check reading of standard instruments. Breaks in the record occur, owing to unforeseen stoppage of the instruments, or inability to make the ascent at the appointed time.

France stands unrivalled in her superb chain of summit stations on the Puy de Dôme (4800 ft.) in Auvergne, on the Pic du Midi (9440 ft.) in the Pyrenees, on the Mont Ventoux (6250 ft.) in Provence, and on the Aigoual (5150 ft.) in the Cevennes, whose construction has cost the national and provincial Governments hundreds of thousands of dollars and years of time. They are generally defective in having no co-operating base stations, and their observations have not been published in detail. In 1890, M. Vallot, a devoted Alpinist and meteorologist, established several stations on and near Mont Blanc, from which records have been obtained each summer since. The highest of these stations, at the Rochers des Bosses, 14,320 ft., is provided with many self-recording instruments operating two weeks without attention, which are looked after by the owner or his guides each week or two during the summer. The Observatory of M. Janssen, sunk in the snow on the very top of Mount Blanc, 1460 ft. higher, is not yet in operation, but a meteorograph has been made for it in Paris, which will continuously record all the meteorological elements during a period of three months without attention. A similar instrument is being constructed at Blue Hill, by Mr. Fergusson, for Prof. Pickering's station on El Misti.

On the Eiffel Tower in Paris are instruments 980 ft. above the ground, which give more nearly the conditions prevailing in the free air than do any others permanently at this elevation. They record at the Central Meteorological Office, a quarter of a mile distant, side by side with similar instruments exposed near the ground.

Among the German and Austrian stations, that on the Sonnblick, a peak of the Austrian Alps, 10,170 ft. high, and the highest permanently occupied observatory in Europe, stands pre-eminent, having furnished very valuable results under Dr. Hann's direction.

[1] Abstract of a paper by Mr. A. Lawrence Rotch, read before the Boston Scientific Society.

Switzerland, which since 1873 had maintained stations in mountain passes, &c., has now on the Säntis (8200 ft.) in the canton of Appenzell, one of the best located and equipped summit stations in the world; and in Italy an observatory on Monte Cimone (7100 ft.) in the Apennines, near Lucca, has recently been completed.

On Ben Nevis, the highest mountain in Great Britain (4400 ft.), there is a remarkable station where during ten years an unbroken series of hourly observations has been maintained. There is a base station at sea-level, and the advantageous situation on the west coast of Scotland renders the results of the observations, which have been discussed by Dr. Buchan, of great value.

It is impossible to even enumerate all that has been gained from these high-level observations, but the chief results attained, or still sought, may be thus summarised: Determination of normal decrease of temperature and humidity with elevation; abnormal changes with elevation in cyclones (or areas of low pressure near the ground) and in anti-cyclones (or areas of high pressure near the ground); height to which these cyclones and anti-cyclones persist, and the circulation of the air around each at various levels.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—At the Encaenia, or Commemoration of Oxford Founders, held on June 26, the honorary degree of D.C.L. was conferred upon Sir W. H. Flower, Prof. Michael Foster, M. Edward Naville, the distinguished Swiss Egyptologist, and Sir A. W. Franks, President of the Society of Antiquaries.

Sir J. E. Gorst has succeeded Mr. Acland as Vice-President of the Council for Education.

Mr. Herbert Hancock, Mathematical and Physics master in Bancroft's School, Woodford, London, has just been appointed to the headmastership of the Hipperholme Grammar School, an important science centre for the North of England.

At a Convocation of Durham University on Tuesday, June 25, the Sub-Warden announced that the new Charter had been received by which power is given to the University to confer degrees upon women in all faculties except Divinity. Among a large number of degrees conferred was that of Bachelor of Science on Miss Ella Mary Bryant, Durham College of Science, Newcastle.

In consequence of the shortly ensuing General Election, the annual meeting of the National Association for the Promotion of Technical and Secondary Education, and the Conference of representatives of Technical Education Committees, which had been arranged to take place in London on July 11, have been postponed.

On Thursday last a very successful and numerously attended conversazione was held at University College, London. The guests were received on the grand staircase by the President (Sir John Erichsen, Bart., F.R.S.) and Deans of Faculties. The various scientific departments of the College were thrown open, and many interesting exhibits contributed to the success of the evening. Among the latter were included the spectra of argon and helium, various electrical and physical experiments, living seaweeds and marine animals, new models of dividing nuclei, &c.

The University of London has conferred the degree of Doctor of Science, without examination, on Mr. Th. Groome, Professor of Natural History at the Royal Agricultural College, Cirencester, in recognition of the merits of his original researches and published papers.

The Berlin correspondent of the *Lancet* writes as follows:—"The publication of a rumour that the authorities intend to abolish the University of Jena, has caused a stir in the scientific world, the university being one of the oldest in Germany, and having often occupied a leading position. Financial reasons are said to have induced the authorities to arrive at this decision. The constitution of the University of Jena is somewhat peculiar. It is not under the jurisdiction of a single State, but belongs jointly to four States of Thuringia, viz., Saxe-Weimar, Meiningen, Coburg, and Altenburg. The Governments of those small States entirely control the affairs of the university. If, for instance, a new professor is to be appointed they must all consent to his nomination. To put a stop to the further propagation of this rumour, the official journals of the four united Governments declare that the continued existence of this venerable university is assured both by public grants and by large donations recently made by old pupils and others. This communication has been received with general satisfaction, particularly in the town of Jena itself, which is entirely dependent upon the university."

SCIENTIFIC SERIALS.

The Mathematical Gazette, No. 5 (May 1895).—This number opens with a paper read by Dr. C. Taylor at the annual meeting of the A.I.G.T. in January last, of which the title is "The Syllabus of Geometrical Conics." In it the writer passes in review what he has done in the subject since his first contribution to the *Messenger* in 1862. Amongst other reasons for writing at this date, Dr. Taylor states: "I have, as I think, arrived at something like finality in my own view of the way in which the subject should be approached." It is on this ground that we commend the author's paper to persons interested in the teaching of geometrical conics. They will derive profit from it. The second of the mathematical worthies noticed by Mr. Heppel is John Dee, noteworthy from his contributions to Billingsley's translation of Euclid. The notes, solutions of *Gazette* questions, solutions of examination questions, and questions for solution, which are all very useful for the readers addressed, are, with the enlarged form of the journal, greatly increased in number and variety. Several recent text-books are also the subject of judicious and discriminating criticism. The *Gazette* should certainly have a successful career.

American Journal of Mathematics, vol. xvii. No. 3.—On irrational covariants of certain binary forms, by E. Study, discusses the most important covariants of binary cubics and quartics and of some other special binary forms. After paying tribute to the methods of Cayley and Clebsch, the author gives his reasons for working the whole subject over again. By means of a carefully chosen system of notation, he presents his results, as he believes, in a form that will be useful to those who have to deal with the numerous applications of the binary quantics of the lowest orders. In some detail (pp. 185–215) he examines the cubic, and the quartic and octahedron, and points out several small numerical errors in previously obtained results. The same writer contributes an article on the connection between binary quartics and elliptic functions. This is an application of the theory developed in the previous article to elliptic functions. In it he compares the relations among the rational and irrational covariants of a quartic with the identities among the four theta-functions; by this means a new light is thrown upon the familiar formulæ, and at the same time a number of new results are derived, which make the theory in question, the author states, in a certain sense *complete*. Stress is laid upon the fact that all the results are obtained by means of *actual calculations*, and that no use is made of the method of indeterminate coefficients.—Semi-combinants as concomitants of affiliants, by H. S. White, opens up a new path apparently (pp. 234–265): "I consider all ground forms that are included in the conjunctive of the system, and those of them that satisfy invariant equations of suitable order, linear in their coefficients, I designate as *affiliant* ground forms." The paper shows that not only is every semi-combinant ground form an affiliant, but also every affiliant ground form is a semi-combinant. Three short notes follow, viz.: Simplification of Gauss's third proof that every algebraic equation has a root, by M. Böcher, a note read before the American Mathematical Society (*cf.* Nature, p. 189): note sur les lignes cycloïdales, by R. de Saussure; and note on lines of curvature, by T. H. Taliaferro.

SOCIETIES AND ACADEMIES.

London.

Royal Society, April 25.—"*Acokanthera Schimperi*: Natural History, Chemistry, and Pharmacology." By Prof. Thomas R. Fraser, F.R.S., and Dr. Joseph Tillie.

Specimens of the wood from which the Wa Nyika, Wa Gyriama and Wa Nyika arrow-poison is prepared have been examined by us and referred to the genus *Acokanthera*, and

leaves, flowers, and fruit, each taken from the same individual tree, having also been sent to us, we have been enabled to determine that the wood of the species *Acokanthera Schimperi*, Benth. and Hook. (*Carissa Schimperi*, A.DC.), is used by the Wa Nyika and other tribes inhabiting the coast regions near Mombasa in preparing their arrow-poisons.

The arrow-poisons of these tribes usually contains a crystalline glucosidal active principle, which, in its chemical properties and pharmacological action, is identical with the active principle also separated by us from the wood of *Acokanthera Schimperi*.

The complete recognition of the species of *Acokanthera* is of primary importance, because several supplies of the wood of unidentified species of *Acokanthera* sent to us from East Equatorial Africa yielded only a glucosidal active principle which was amorphous.

The characters of the crystalline active principle which we have separated from the wood of the fully identified species, *Acokanthera Schimperi*, Benth. and Hook., agree with those of the crystalline active principle ouabain, separated by Arnaud from the wood of the unidentified species of *Acokanthera*, provisionally named *Ouabaio*, obtained from North Somaliland, and also from the seeds of an unidentified species of *Strophanthus*, obtained from West Africa. As, however, the name ouabain is used for three quite different substances, two of which are amorphous, we would suggest that, in accordance with a usual custom, the crystalline active principle of *Acokanthera Schimperi* should be named acokantherin, and not ouabain.

The work accomplished by Arnott and by Haines in 1853, by Ringer in 1880, by Rochebraune and Arnaud in 1881, by Laborde in 1887, by Langlois and Varigny, by Gley and Rondeau, and by Gley in 1888, by Sailer in 1891, by Paschkis in 1892, and by Lewin in 1893, has been more fully described in this paper than in our preliminary notice of March 23, 1893.

A detailed examination of the pharmacological action of acokantherin has not led to the discovery of any important qualitative differences between its action and that of *Strophanthus hispidus* and of its active principle strophanthin, which was described by one of us in 1870, in 1872, and in 1890. As, however, a special interest must be attached to the effects upon the circulation, the experiments upon the heart, blood-vessels, and blood-pressure are described with more detail than those upon other systems.

The predominant action of acokantherin is that exerted upon striped muscle, and, because of this action, with possibly an action upon the intrinsic cardio-motor ganglia, the chief effect is produced upon the heart, while the influence exerted upon the cardio-respiratory centres in the medulla is relatively slight or secondary.

May 30.—"On the Effect of Pressure of the Surrounding Gas on the Temperature of the Crater of an Electric Arc Light. Preliminary Notes of Observations made at Daramona, Streete, Co. Westmeath." By W. E. Wilson.

Of late years it has often been assumed that the temperature of the crater forming the positive pole of the electric arc is that of the boiling of carbon. The most modern determinations give this point as about 3300°–3500° C.

Solar physicists have thought that the photosphere of the sun consists of a layer of clouds formed of particles of solid carbon. As the temperature of these clouds is certainly not below 8000° C., it seems very difficult to explain how carbon can be boiling in the arc at 3500° and yet remain in the solid form in the sun at 8000°. Pressure in the solar atmosphere seemed to be the most likely cause of this, and yet, from other physical reasons, this seemed not probable.

In order to investigate whether increased pressure in the gas surrounding an electric arc would raise the temperature of the crater, the author used a strong cast-iron box in the interior of which an electric arc light could be maintained. At the side of the box was inserted a glass lens, by which an image of the crater was formed at a distance of 80 cm. When this image was allowed to fall on the aperture of a Boys radio-micrometer, the deflections of this instrument showed any variations in the radiation from the crater. The author then describes the experiments made with this apparatus, and shows that by increasing the pressure of the gas in the box the temperature of the crater is considerably lowered intead of being raised, and he concludes that these experiments seem to show that the temperature of the crater, like that of a filament in an incandescent lamp, depends on how much it is cooled by the surrounding atmosphere, and not on its being the temperature at which the vapour of carbon has the same pressure as the surrounding atmosphere. That carbon volatilises in some form at comparatively low temperatures seems likely, from the way in which the carbon of incandescent lamp filaments is transferred to the glass. The pressure of the vapour of carbon in the arc may consequently be very small, and further it would seem that the supposition of high pressures in the solar photosphere, which has been referred to in the beginning of this paper, is not borne out by these experiments, and that carbon may exist there in the solid form at very high temperatures although the pressures are comparatively low.

June 13.—"Further Observations on the Organisation of the Fossil Plants of the Coal Measures. Part 3, *Lyginodendron* and *Heterangium*." By W. C. Williamson, F.R.S., and D. H. Scott, F.R.S.

The authors sum up their conclusions as follows:—

The vegetative organs of these genera show a remarkable combination of fern-like and cycadean characters. The leaves of *Lyginodendron*, which are now well known, are so like fern-leaves, not only in form and venation but in minute structure, that if they stood alone they would, without hesitation, be referred to Filices. Although many leaves simulate those of ferns in external characters (*Stangeria*, *Thalictrum*, &c.), none are known which at the same time show the characteristic anatomy of fern-leaves. Hence we are led to attach great weight to the characters of the *Lyginodendron* foliage. That of *Heterangium*, though less well preserved, was evidently of the same type.

In *Heterangium* the primary structure of the stem is much like that of a monostelic fern such as *Gleichenia*, but the leaf-trace bundles closely resemble the foliar bundles of a Cycad.

In *Lyginodendron* the whole structure of the *stem* suggests a Cycad, but with the remarkable peculiarity that the bundles here have the structure which in Cycadeæ is usually (though not always) limited to those of the leaf. The cycadean characters are too marked to be accidental, though the general anatomy of *Lyginodendron* is not inconsistent with a close relationship to ferns, for in *Osmunda* we have a monostelic fern, with a large pith, collateral bundles in the stem, and concentric ones in the leaf. The mere occurrence of secondary growth in a fern-like plant is not surprising, considering that it takes place in *Botrychium* and *Helminthostachys* at the present day.

In various respects *Lyginodendron* and *Heterangium* have points in common with Gleicheniaceæ, Osmundaceæ, Marattiaceæ, Ophioglosseæ, and Cycadeæ. The view of their affinities, which we suggest, is that they are derivatives of an ancient generalised race of ferns, from which they have already diverged considerably in the cycadean direction. Of the two genera, *Heterangium* appears to be geologically the more ancient, and certainly stands nearer to the filicinean stock. *Lyginodendron*, while retaining conspicuous fern-like characters, has advanced much further on cycadean lines. This view by no means involves the improbable assumption that these plants were the actual ancestors of existing Cycadeæ. How far their divergence from the fern stock had proceeded cannot be determined until we are acquainted with their organs of reproduction.

The existence of a fossil group on the border land of ferns and Cycads seems now to be well established. Count Solms-Laubach places his *Protopitys* in this position, which is probably shared by *Myeloxylon* and *Poroxylon*. Messrs. Bertrand and Renault have indeed endeavoured to derive the last-named genus from Lycopodiaceæ, and have extended the same view to *Lyginodendron* and *Heterangium*. In the latter cases their theory is completely negatived by the organisation of the leaves, and by many structural details.

The relation of the genera which we have described to those ancient gymnosperms, the *Cordaiteæ*, will form one of the most interesting palæobotanical problems of the future.

The paper is illustrated by micro-photographs and by camera-lucida drawings.

Geological Society, June 19.—Dr. Henry Woodward, F.R.S., President, in the chair.—On the occurrence of radiolaria in chalk, by W. Hill and A. J. Jukes-Browne. The authors noticed the rarity of records of Cretaceous radiolaria, and alluded to those which have been made, including those by Rüst and Sollas. They recently discovered spherical bodies resembling in form and general appearance certain calcified and partially destroyed radiolarian tests from some of the Barbadian

rocks; microscopic examination of these proved that many of them, at any rate, are radiolaria. The bodies occur in the nodules of the lower beds of the Melbourn rock at Melbourn, Royston, near Hitchin, Leagrave, near Luton, Pitstone and Tring, Watlington, the Richmond boring, the lower part of the "Grit Bed" at Dover, Sutton Waldron and Burcombe (Dorset), and in a nodular chalk which may be considered as the equivalent of the Melbourn rock from Bindon Cliffs, near Axmouth, Devon. Similar organisms have recently been found in the chalk marl of Lincolnshire, Yorkshire, and Norfolk, but have not been noticed in any other parts of the chalk. It was suggested that they occurred in many portions of the chalk-ooze, but were usually rapidly and completely dissolved, and contributed to that solution of silica which furnished the substance of flint-nodules; and the authors concluded that the preservation of traces of the radiolaria in the nodules of the Melbourn rock was due to some specially favourable conditions. A description of the changes undergone by Barbadian radiolaria was given to illustrate the instability of radiolarian tests. All stages were traceable, from the perfect siliceous test to a structureless ball or disc filled with calcareous matter, or a mere patch of clear crystalline material. A description of forms recognised in the nodules of the Melbourn rock was given.—The crush-conglomerates of the Isle of Man, by G. W. Lamplugh, with an appendix by W. W. Watts. The Skiddaw slates of the Isle of Man have everywhere undergone intense shearing, and on the north-west side of the main stratigraphical axis actual disruption of the bedding with the resultant formation of breccia or crush-conglomerate on a large scale has taken place. This structure attains its widest development on the north side of the central valley, though it is noted on a more limited scale in a few localities farther south. The sections described showed the gradual smashing into fragments of highly contorted strata until every trace of the original bedding is lost, and a "crush-conglomerate" with lenticular and partly rounded inclusions is formed. The rocks described in Mr. Watts's appendix were grouped in four classes. Firstly, the grits and slates which had been crushed but had not been converted into crush-conglomerates; secondly, the crush-conglomerates themselves, and the fragments which they contain; thirdly, the dykes of decomposed dolerite (greenstone) and fresh later dolerite which penetrate the conglomerate; fourthly, a portion of the crush-conglomerate metamorphosed by these intrusions. The chief point of interest was brought out by the examination of the fragments in the conglomerate. All stages of crushing could be traced, until the grit-fragments had a structure which was a mere miniature of the crush-conglomerate itself; that is to say, if the crush-conglomerate be regarded as made of "fragments" of hard rocks enclosed in crushed "matrix" of soft rocks, a host of intermediate varieties with varying resistances will occur.—The chalky clay of the Fenland and its borders; its constitution, origin, distribution, and age, by Sir Henry H. Howorth, M.P., F.R.S. The distribution of the clay (so often termed chalky *boulder* clay) was noticed. The paucity of foreign stones was noted as compared with natives, and the similarity of the matrix of the chalky clay to the material of the older deposits of the neighbourhood. The author maintained that the contents of the clay indicate movement of material from west to east in some places, as shown by Jurassic fossils in the East Anglian chalky clay, and from east to west in others; in fact, that movement took place in sporadic lines diverging from the Wash and the Fens. He appealed to the amount of disintegration that had taken place to furnish the material for the clay, the shape of the stones in the clay, and the distribution of the clay itself, as evidence against the action of land-ice or icebergs, and maintained that there was no evidence of submergence at the time the clay was formed; and criticised the attempts made to explain the formation of the clay by water produced by the melting of ice.—On the occurrence of *Spirorbis*-limestone and thin coals in the so-called Permian rocks of Wyre Forest; with considerations as to the systematic position of the "Permians" of Salopian type, by T. Crosbee Cantrill. In South Staffordshire a thick series of red rocks—the so-called Lower Permian—overlies the ordinary yellow and grey coal measures, and underlies the Triassic rocks. They consist of sandstones, marls, calcareous conglomerates, and breccias, having a general red or purplish-red colour. Sinkings have shown that these red rocks must be regarded as of Upper Coal Measure age, because their included fossils have an Upper Coal Measure *facies*. The rocks contain bands of limestone characterised by the presence of *Spirorbis pusillus*: those parts of the series which have not yielded Coal Measure fossils being apparently similar lithologically to those which have yielded them. The evidence furnished by the deposits of the Forest of Wyre (= Enville) district also led the author to regard the red rocks associated with *Spirorbis*-limestone and coals as Upper Coal Measures, exhibiting a gradual passing away of Coal Measure conditions and the incoming of those of new red sandstone times.

Linnean Society, June 20.—Mr. C. B. Clarke, President, in the chair.—Mr. F. Enock exhibited and made some remarks upon a living specimen of an aquatic hymenopterous insect, *Polynema natans*, Lubbock.—Messrs. E. Baker and C. Reid exhibited some rare plants from the limestone hills, Co. Kerry, including *Pinguicula grandiflora*, Lam. contrasted with *P. vulgaris*, and *Saxifraga Geum* contrasted with *S. umbrosa*, with a view of determining their value as sub-species or geographical races.—Mr. Carruthers exhibited some feathers of a cuckoo taken at Whitchurch, Shropshire, on May 23 last, amongst which were some moulted feathers which were held connected with the new feathers which had replaced them by means of the barbed seed capsules of a sub-tropical grass, *Cenchrus echinatus*.—On behalf of Mr. S. Loat, there was exhibited a cuckoo's egg, taken from the nest of a hedge-sparrow, together with five white eggs of that species, an abnormality not often met with. An examination of these eggs under the microscope showed that, in regard to the texture or grain of the shell, they agreed with eggs of the hedge-sparrow, and not with those of the robin, of which white varieties are not so rare.—Mr. George West then gave the substance of a paper on some North American *Desmidieæ*, describing the characters of several new species with the aid of specially prepared lantern slides.—Mr. A. Vaughan Jennings gave a detailed account of the structure of the Isopod genus *Ourozeuktes*, upon which a most instructive criticism was offered by the Rev. J. R. Stebbing, who was present as a visitor; some further remarks being offered by Mr. W. P. Sladen.—Mr. F. N. Williams communicated the salient points in a critical paper which he had prepared, entitled "A Revision of the Genus *Silene*." On behalf of Mr. E. R. Waite, Prof. Howes gave an abstract of a well illustrated paper on "The Egg-cases of Port Jackson Sharks," and exhibited several spirit specimens in further elucidation of the subject.—This meeting terminated the session.

PARIS.

Academy of Sciences, June 24.—M. Marey in the chair.—On the gradual extinction of an ocean-roller at great distances from its place of production: formation of equations of the problem, by M. J. Boussinesq.—New studies on the fluorescence of argon and on its combination with the elements of benzene, by M. Berthelot. With the help of M. Deslandres, the author has made a more complete spectroscopic examination of the emerald-green light produced by the fluorescence of argon under the influence of the silent electric discharge. The significance of the various rays observed or photographed is discussed. Finally, the conclusion is drawn that this fluorescence is definitely due to a condensation compound of argon; it points to the probable existence of a complex state of equilibrium in which argon, mercury, and the elements of benzene are concerned.—On the campholenic lactones, by MM. Berthelot and Rivals. The lactones have heats of formation greater than those of the isomeric acids.—On the heats of solution and neutralisation of campholenic acids, by M. Berthelot.—Reduction of silica by carbon, by M. Henri Moissan. With a current of 1000 amperes at 50 volts, the author has obtained characteristic crystals of silicon, but always mixed with carbon silicide. At the high temperature attained, carbon from the crucible reduces the silica of the charge.—Observations on a note, by MM. Barbier and Bouveault, on the products of condensation of valeric aldehyde, by M. C. Friedel.—On the integration of linear equations by the aid of definite integrals, by M. Ludwig Schlesinger.—On the determination of the ratio of the two specific heats for air, by M. G. Maneuvrier. A new method and new apparatus are described. The experimental determination of the ratio of the specific heats has yielded the following numbers:—Air, $\gamma = 1\cdot3924$; carbon dioxide, $\gamma = 1\cdot298$; hydrogen, $\gamma = 1\cdot384$ under the ordinary conditions of temperature and pressure.—On the propagation of sound in a cylindrical tube, by MM. J. Violle and Th. Vautier. An account of the conduction of musical sounds over long distances by pipes of wide diameter.—On the refraction and dispersion of ultra-violet radiations in some crystallised substances,

by M. G. Adolphe Borel.—On the variations of "écrouissage" of metals, by M. Faurie.—On punching, by M. Ch. Fremont. An experimental inquiry into the conditions affecting the amount of play necessary between a punch and its bed. The results lead to the conclusions: (1) That the maximum effort in punching metals is independent of the clearance space in the ordinary practical conditions; (2) that the clearance space or play is a function of the thickness of the metal to be punched, and not of the diameter of the punch; (3) that it is also a function of the elongation of the metal, but in a less proportion; (4) that the play allowed ought to be about a fifth of the thickness of the metal punched. A figure is given illustrating the form of punch best adapted for piercing perfect holes.—Properties of solid carbonic acid, by MM. P. Villard and R. Jarry. Carbon dioxide solidifies and melts under a pressure of 5·1 atmospheres at $-56{\cdot}7$ C. In free air, the solid has the temperature $-79°$; ether does not lower this temperature, as has been hitherto supposed, but methyl chloride and solid carbon dioxide produce a temperature of -85 C. At a pressure of 5 mm. the solid has reached a temperature of -125.—On M. Guye's hypothesis, by M. A. Colson.—On the alcohols derived from a dextro-rotatory turpentine, eucalyptene, by MM. G. Bouchardat and Tardy.—Condensation of the unsaturated alcohols of the fatty series with dimethylketone.—Synthesis of aromatic hydrocarbons, by MM. Ph. Barbier and L. Bouveault.—Double compounds of the fatty and aromatic nitriles with aluminium chloride, by M. G. Perrier.—Action of the air on raisin must, by M. V. Martinand.—On the preservation of wheat, by M. Balland.—On the sexual dimorphism of the Nautilus, by M. A. Vayssière.—On the variations of apparent clearness with the distance, and on a law of these variations as a function of the luminous intensity, by M. Charles Henry.—Seismic observations made at Grenoble, by M. Kilian.—On the dissolved gases at the bottom of Lake Geneva, by MM. André Delebecque and Alexander Le Royer.—The effects of the synodic and anomalistic revolutions of the moon upon the distribution of pressures in the season of winter, by M. A. Poincare.—On the subject of the treatment of the bites of venomous serpents by chloride of lime and by antitoxic serum, by M. A. Calmette.

Amsterdam.

Royal Academy of Sciences, May 25.—Prof. Van de Sande-Bakhuyzen in the chair.—Prof. J. C. Kapteyn showed how the following three laws may be deduced from observations: (1) the law according to which the linear velocities of the stars are distributed; (2) the law according to which the number of stars per unit of volume varies with the distance from the sun; (3) the law according to which the absolute stellar magnitudes (magnitude at unit of distance) are distributed. The hypotheses on which the author's conclusions were based were as follows: (*a*) the real movements of every degree of magnitude of the stars in space are equally numerous in every direction; (*b*) the law of the distribution of stellar velocities does not vary with the distance from the sun; (*c*) the function representing this law has but a single maximum.—Prof. Engelmann treated of reciprocal and irreciprocal conductivity of muscles, with special relation to the theory of the heart.—Prof. Van der Waals treated of the relation between the critical temperature and the critical pressure for a mixture (tacnodal curve).—Prof. H. Behrens described some cases of artificial dichroism. Strong dichroism were observed on flax and hemp fibres after having been dyed with congo-red or benzo-azurine. A similar result was obtained with the majority of the tetrazo-dyestuffs used for dying cotton; whereas, by the application of naphthol orange, croceine scarlet, and other similar dyestuffs, no dichroism was developed. Only three basic dyestuffs were found to be capable of making flax dichroic. Among other fibres the straw fibre comes next to flax and hemp; the cotton and the wood fibres stand lower in the scale; silk requires to be dyed a deep blue with an acidulated solution of benzo-azurine, and on wood the phenomenon of artificial dichroism has not been produced by any of the colouring matters named above. Flax and hemp are strongly polarising, and can be rendered strongly dichroic, while in cotton these two qualities are found in a smaller degree; but silk, ranging above straw in polarisation, falls far below cotton as to artificial dichroism. The phenomenon seems to be of a complex nature, not explained by assuming a combination of ordinary absorption with ordinary double refraction.—Prof. Van der Waals presented a paper by Prof. W. H. Julius, entitled "On an arrangement for protecting measuring instruments from the ordinary vibrations of the ground."—Prof. Kamerlingh Onnes presented, (1) on behalf of Prof. W. Einthoven, an isolation arrangement against vibrations of contiguous bodies; (2) on behalf of Dr. J. P. Kuenen, the influence of gravitation upon the critical phenomena of simple substances and mixtures.

THURSDAY, JULY 11, 1895.

THE TEACHING OF PATHOLOGY.

The Elements of Pathological Histology. By Dr. A. Weichselbaum. Translated by W. R. Dawson. London: Longmans, Green, and Co., 1895.

THOSE who have watched the progress of pathological teaching, in this country especially, must have recognised that during recent years its scope has become much wider, or that at least there is a tendency towards broader conceptions. Cohnheim made an attempt to cast off the narrow fetters of Morbid Anatomy, and to instil into his pupils that wonderful enthusiasm which he himself felt for General Pathology, or, as we may term it, "Morbid Physiology." His "Vorlesungen uber Allgemeine Pathologie" still form a monumental record of what he has achieved, and his method must and should be the ideal of every teacher of pathology. Strange to say with his death things reverted into the old groove, and until recently, pathological teaching restricted itself almost exclusively to Morbid Anatomy. "Nec silet mors" is the motto of the Pathological Society: it is not appropriate, because pathology deals not merely with death; its soul and essence, however morbid, is "life." Bacteriology, now a recognised branch of pathology, in spite of all the harm it has wrought, has achieved this, that it has carried us away from the dead-house to the laboratory, and has awakened in us the spirit of experimental inquiry.

Bacteriology should be regarded, however, as an adjunct to pathology, *i.e.* so far as it applies to disease; beyond that it belongs to botany. Every bacteriologist should be a pathologist, and every pathologist should possess an adequate knowledge of physiology as well as a complete mastery over morbid anatomy. The day is to be regretted when we follow the footsteps of our continental brethren, and become mere specialists in the art of growing bacteria and of immunisation. It is not intended to give the erroneous impression that morbid anatomy is not pathology—it still is, as ever it was, the most important partner from the student's as well as the investigator's point of view and for practical purposes; but this must be insisted upon, that the morbid physiology of the body and of disease has been too much neglected. This becomes evident when we look through our text-books and manuals of pathology. Year after year we have fresh treatises on morbid anatomy and histology, or on bacteriology, but there is, if we except Cohnheim's classical work, hardly a book on the pathology of disease and its processes. If we wish to learn this, we have to turn to our standard works on medicine or to the journals. The present volume, the subject of this review, deals exclusively with morbid histology and bacteriology, and for that reason, however valuable it may be, it may be asked whether there was the need for Dr. Dawson to give up so much time to its translation. We have a sufficient number of similar works already; why give us a stone when it is bread we want? Prof. Weichselbaum's name is sufficient to lead us to expect a useful book on bacteriology, and a satisfactory one on morbid histology; more we cannot look for from that source. A careful perusal of the translation justifies our expectations.

Of 441 pages, more than eighty are devoted exclusively to bacteriology, *i.e.* to the description of bacteriological methods, and to a *résumé* of the general principles. If we keep in mind that under each organ also subsequently all the various infective and microbic lesions are carefully discussed, it seems to us that the author has given undue prominence to this, which is, after all, a small part of his subject.

It is difficult to serve two masters, and the result must be that for bacteriological methods and principles we shall continue to consult special works: they are numerous, and it would be difficult to find works of greater usefulness than Prof. C. Frankel's excellent text-book or the elaborate compilation of Dr. Heim. The directions given for bacterial staining or cultivation are too meagre to be of much use to the beginner. Gram's well-known method, *e.g.*, is described thus: "Sections are placed for half an hour in aniline gentian violet, then for two or three minutes in iodine and potassium iodide, and then in alcohol, which is changed as it becomes coloured. Finally they are cleared and mounted." One can imagine the poor tyro mournfully contemplating the result of those instructions. We therefore adhere to the opinion that in works intended for students, too much should not be offered between the covers; but, if a comprehensive treatise is intended, fulness and completeness of directions and instructions are imperative. The descriptions of the micro-organisms, though short, are succinct and good, so far as they go; but the German edition having appeared in 1892, new discoveries and altered views are wanting, and the briefness is often exasperating.

Now as to the purely anatomical or histological part of the book, it also suffers from shortness, and we must confess that we have works in the English language which are sure to occupy a higher position than this translated importation. Useless Dr. Dawson's work certainly is not; the beautiful illustrations and a chapter on blood examination, short though it be, recommend it. Many of the illustrations are new and original, and are exactly the kind of representation wanted to bring out the salient points in a histological specimen. The English publishers also have done all they could to give the work a good appearance, and altogether it is a pleasant book to possess. It is essentially an annotated picture-book; but as a picture-book it is excellent, and will be of great use to those who consider the study of morbid anatomy and histology a form of "Anschauungsunterricht"; and, indeed, much can be learnt from good pictures. One point this work brings home to us in a painful manner, viz. the decline of pathological anatomy. Bacteriology swamps everything. On the continent, professorial chairs of pathology are occupied by bacteriologists, and the instruction of hygiene is also given over to bacteriologists. The result is that sound pathological anatomy is pushed steadily into the background. So far in this country, fortunately, we have suffered less; in principle, at least, we still consider bacteriology merely a fraction or an element of pathology, but already the spectre has risen, and unless we take care, we also shall be ruled by the bacillus, and find contentment in the haven of mediocrity

which so-called bacteriological research opens up to those who, incapable of doing real pathological or physiological work, have leisure to practise bacteriology as a "fireside" game.

In conclusion, a word in praise of the translator and editor: he has done his work excellently, so well, in fact, that one cannot help regretting that he used his gifts and expended his labours on a book hardly worthy of so much conscientious energy and patience. The translation is better than the original in arrangement, type and general "get up." Since it is pleasing to most to possess a nice book, and one which is at the same time instructive, in spite of some remarks which may appear severer than they are meant to be, we may recommend it safely as an addition to the student's library.

A. A. Kanthack.

THE NATURAL HISTORY OF AQUATIC INSECTS.

The Natural History of Aquatic Insects. By Prof. L. C. Miall, F.R.S. London: Macmillan and Co., 1895.

PERHAPS no country possesses so many amateur naturalists as England, at least in proportion to its population, and it is not without significance in this direction that many of our best professional men of science have not thought it undignified to furnish sound information on their special subjects in a popular and yet accurate manner. The present work is a good example of this, and Prof. Miall deserves praise for the admirable account he has put together of the insect inhabitants of our lakes, ponds, and watercourses.

Of course it has not been without forerunners. One of the last works of that well-known writer on popular science, the late Rev. J. G. Wood, was entitled "The Brook and its Banks," and covered much the same ground; but one may say, without any disparagement, that his book was more picturesque or anecdotal natural history than strictly scientific.

Again, Prof. Miall, like every subsequent writer on entomological subjects, is greatly indebted to the laborious researches of Swammerdam, Réaumur, Lyonnet, and others of the early naturalists, but in every case this is freely acknowledged, and he adduces their works as models of patient investigation on the living animal, particularly worthy of emulation at the present time, when attention is almost exclusively paid to phylogeny and classification, to the neglect of the actual life history, where so much still remains to be discovered. Some essential matters are briefly treated in an introductory chapter, such as the equilibrium of aquatic insects, the tension of the surface film of water and its effect on small objects, and also the question of the original habitat of insects, whether terrestrial or aquatic, which Prof. Miall confidently decides as the former, mainly from the general presence of tracheæ and functionally active spiracles even in purely aquatic insects, showing that such as are fitted for breathing only dissolved air are those that deviate from the general and primitive rule. The chief aquatic Coleoptera are taken first, and certain curious structures in the larva and imago of several families somewhat fully described. Among these we comment on the mouth organs of the larva of Dytiscus, which have been a subject of controversy from the time of Swammerdam and De Geer up to Meinert, Schiödte and Burgess, whose description has been verified by Prof. Miall, and also the well-known tarsal clasping suckers of the adult male, the real structure and action of which was first pointed out by Lowne. The method of respiration in the adult Hydrophilus is well explained, and the extraordinary arrangement for obtaining air from cavities in submerged roots adopted by the larva of Donacia, as discovered by Siebold. Flies with aquatic larva receive considerable attention, no less than 122 pages being devoted to these extremely interesting creatures, which from their transparence, in many cases, have long been favourite objects with microscopists. The development of the Gnat, Chironomus, Simulium, Eristalis, and numerous others is fully gone into, and the amateur naturalist will find plenty of occupation, and derive no little benefit, by following out their structure with this book as his guide. There is a short account of that very beautiful aquatic hymenopterous insect Polynema, which, according to Ganin, deposits its eggs in the eggs of a Dragon-fly; and another form, Agriotypus, said to be parasitic on a Caddis-worm. Caddis-flies (Trichoptera), Sialis, the alder-fly of anglers, the stone-flies, may-flies, dragon-flies, pond-skaters, water-boatmen, and all the rest of the host of insects which pass a large part of their existence in the water, are dealt with in due order, and the descriptions are frequently supplemented with bibliographies, which will be useful to those who require further information on special points. A word must be said for the illustrations, which in large part have been drawn by Mr. A. R. Hammond for this work; they are extremely clear and well executed—quite a relief, indeed, from the old clichés usually considered good enough by publishers to adorn a work of this kind. Altogether, the "Natural History of Aquatic Insects" is a very good and useful specimen of its class.

OUR BOOK SHELF.

The Royal Natural History. Edited by Richard Lydekker, F.R.S., &c. Volume iii. (London: Warne, 1895.)

THE third volume of this excellent "Natural History" finishes the mammals, and commences the birds.

Among the former the Cetaceans, the Rodents, the Edentates with the pouched mammals, and the Monotremes are described at appropriate length. The information is generally up to date, and the illustrations are good. To the notices of the occurrence of Sowerby's whale on the coasts of England and Scotland, may be added that of its being captured some years ago in Brandon Bay, Kerry, the head of the specimen being in the Dublin Museum. The immense group of the Rodents is judiciously treated, most of the more important facts of their history being given. Only six pages are devoted to the egg-laying mammals, and there is no figure of the duckbill's egg.

The chapters on the perching birds and Picariae are contributed by Mr. H. A. Macpherson and Dr. Bowdler Sharpe. "The number of the existing species of birds being in all probability considerably over ten thousand," the authors are obliged to treat of them even in a more condensed form than were the mammals; still the order of Passeres, which includes by far the majority of known birds, is fairly treated, and most of the well-known or interesting birds are alluded to. Dr. Sharpe confesses

his inability to give a diagnosis of the Picariæ, that is in the logical sense, but claims that the group as selected by him possess "certain common features not found among the Passeres." In the last chapter in this volume, he treats of the Jacamars to the Toucans.

Cours Élémentaire d'Électricité. By M. B. Brunhes. Pp. 265. (Paris: Gauthier-Villars et Fils, 1895.)

THE experimental laws and general principles belonging to the study of technical electricity are set forth in this book in an elementary, but strictly scientific, manner. The book reproduces the author's first-year course of theoretical electricity at the Institut industriel du Nord de la France, and its contents furnish just the kind of foundation needed by students of electrical engineering. In several respects, the treatment differs from that generally followed in text-books; hydrodynamic analogues are entirely omitted, and the word potential is not employed, voltage, or E.M.F. between two points, being used to express potential difference.

Off the Mill: Some Occasional Papers. By G. F. Browne, B.D., D.C.L., Bishop of Stepney. Pp. 271. (London: Smith, Elder, and Co., 1895.)

ALPINE climbers, and others who find delight in mountain-peaks and glaciers, may like to read the papers on Alpine subjects reprinted in this volume. The papers originally appeared thirty years ago, and they offer to the present generation of mountaineers an interesting picture of the way in which climbs were then made. The ice-caves in the neighbourhood of Annecy form the subject of one of the papers appealing to scientific readers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Cyclonic Indraught at the Top of an Anticyclone.

BETWEEN June 7 and 12 an anticyclone, with maximum pressure of 30·20 to 30·30 inches, passed slowly from the north-west across southern New England. The isobars formed well-defined ovals, with their longer axes running from south-west to north-east. It was difficult to locate the centre of the anticyclone because the isobars were broken on the side toward the ocean: but, by drawing a line through the stations showing the maximum pressure, the crest or ridge of the anticyclone could be easily located up to the 11th, after which it passed off the coast and its position became somewhat uncertain, although the pressure continued above normal over southern New England until the night of the 12th.

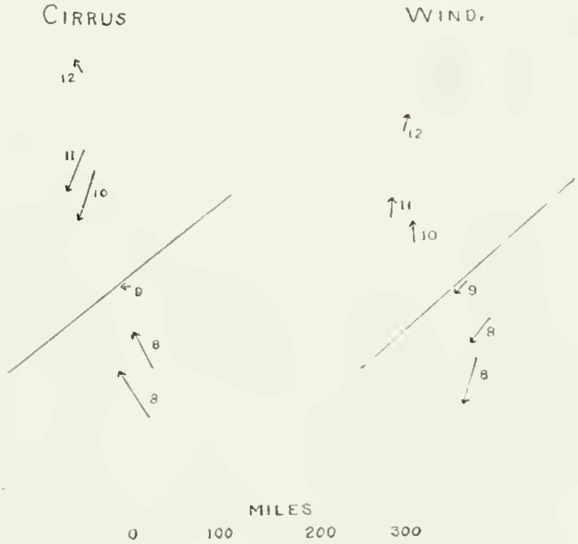
The interest attaching to the anticyclone lies in the fact that cirrus observations obtained on both sides of the line of maximum pressure indicate an indraught at the top of the anticyclone of the same nature as that observed at the bottom of cyclones.

The anticyclone passed nearly centrally over the Blue Hill Meteorological Observatory. As it approached from the north-west, the cirrus clouds on the 8th were observed moving from the south south east. As the line of maximum pressure passed over the observatory on the 9th, the cirrus movement shifted to the north-east, from which direction it was observed on the 10th and 11th. This change corresponds almost exactly with what would be observed in the surface wind should a trough of low pressure pass over Blue Hill from the same direction. On the 12th the cirrus shifted to south, and on the 13th to the west, with the approach of a cyclone from that direction.

The direction of cirrus movement and the mean direction of the wind is recorded at the observatory in degrees of azimuth beginning with the south point. The first is measured with a nephoscope, and the second recorded by a Draper anemoscope. The following table gives the cirrus and corresponding wind observations between the 8th and 10th, no cirrus observations being obtained on the 7th. The velocities of the cirrus were obtained by multiplying the observed relative velocities by a factor to reduce to absolute velocities. This factor was determined from direct measurements of cloud heights and velocities carried on for some time at this observatory. The last column in the table contains the directions in degrees of azimuth of the line of maximum pressure in the anticyclone, taken from the maps of the United States Weather Bureau.

	Cirrus.		Wind.		
	Dir. from.	Veloc. Miles.	Dir. from.	Veloc. Miles.	Line of max. press.
June 8, 8 a.m.	329	48	203	29	50
,, 8, 8 p.m.	320	34	225	23	45
,, 9, 8 a.m.	243	6	233	18	47
,, 10, 5 p.m.	213	34	13	12	60
,, 11, 2 p.m.	245	34	21	14	70
,, 12, 8 a.m.	340 ?	16 ?	47	13	?
,, 12, 5 p.m.	341	18	8	22	?

The changes in the direction of the cirrus and of the surface wind, as related to the line of maximum pressure, is shown graphically in the accompanying diagram. The line of maximum



pressure is indicated in each case by the long slanting line. The arrows fly with the cirrus and with the wind, and the length of the arrows indicate the velocity, though on a different scale in the two cases. The small figures near the arrows give the dates of observation.

Repeated observations of this kind, here and elsewhere, ought to throw some light on the causes of cyclones and anticyclones. If an indraught prevails at the top of the anticyclone of the same nature as the indraught at the earth's surface in a cyclone, it seems difficult to avoid the conclusion that there is an area of low pressure in the upper air above anticyclones, notwithstanding the fact that studies of mountain observations by Hann and others lead to an opposite conclusion. In the present case the inward gradient above appears not to have extended entirely to the outer limit of the anticyclone as indicated by the observations on the 12th.

Direct observations of the anticyclonic inflow must, however, be rare: first, because of the infrequency of cirrus in the proper positions, and the general absence of exact methods of measuring the slow motions observed; second, because there is usually a strong eastward drift in the upper air, which greatly interferes with the anticyclonic circulation, and generally overrides it, so that it only becomes strongly marked under stagnant conditions of the general atmosphere; third, the upper air isobars are usually distorted by strong contrasts of temperature in the area of the anticyclone. But notwithstanding these drawbacks, I am confident that with the increasing attention given to cloud observations, cases like the present will be frequently

observed. With a great many observations the anticyclonic inflow can be brought out by a system of averaging, as shown in the *American Meteorological Journal* for August 1893.

H. HELM CLAYTON.

Blue Hill Meteorological Observatory, June 17.

Effects of a Lightning Flash in Ben Nevis Observatory.

WHENEVER a thunder-storm passes the summit of the Ben, there occurs almost invariably a discharge from metallic bodies in the Observatory, as the cloud is passing away. A flash of greater or less extent is given off the stoves, accompanied by a sharp crack. In January 1890 there was an exceptionally severe flash; "one of the observers was almost knocked down when sitting writing, and the telegraph wire was fused, and all communication stopped for five days." But more destructive than any previous flash was that which occurred this year on June 19, when the Observatory narrowly escaped being destroyed by fire. Between two and three o'clock on that afternoon, repeated clicks on the telegraph instrument were heard by one of the assistants who was sitting in the office; he had been carefully noting the times at which the clicks occurred, when suddenly the whole office was filled with a brilliant flash and deafening roar. A pillar of smoke was discharged from the telegraph instrument and from the stove-pipe, filling the room. So severe was the flash that the assistant, who was quite deafened by the report, thought that his hair had been singed. A second slighter discharge took place immediately after, when the writer had entered the office to commence the fifteen hours observations. The discharge hurled two boxes and a small picture, that were in the vicinity of the lightning protector, across the kitchen, and blew off the button and outer casement of the electric bell in the visitors' room. The solder on the kitchen chimney outside, a copper fastening of the lightning conductor, and many portions of the telegraphic wire and apparatus were fused, and the woodwork of the Observatory was scorched in several places. The great flash occurred at 14 hours $57\frac{1}{2}$ minutes, and the hourly barometric reading was taken at 15 hours, as usual. There was a very heavy fall of snow at the time, equivalent to 0·470 inches of rainfall for the hour, but in the confusion the writer omitted to take the rain-gauge with him, and had to return for it. This was a fortunate incident; for it was only on leaving the office for a second time, that he observed smoke and flame issuing from behind the panelling between the kitchen and the office. Assistance was secured, and the fire—which was in a very awkward and dangerous place—was overcome in good time, and the damage done was very slight.

The damage done to the telegraphic apparatus, however, was serious, and Mr. Crompton, engineer of the Post Office telegraphs, has supplied me with the following information.

The lightning protector was badly fused, the plates showing a patch of fusion as large as a sixpence. This saved the cable from serious damage. All connecting wires within the building were rendered useless. The majority were so heated as to melt the insulation off, and, in one or two cases, the copper conductors were melted by the discharge. In one case, the fusion set fire to the woodwork.

The coils of Neale's sounder were fused and rendered useless. The keys suffered worst of all, the left pedal or "tapper" bearing the strongest evidence of the severity of the discharge. The back contact (platinum), the brass extension holding the same, and the steel spring (platinum-tipped) above, all being fused into one solid amalgam. The pillar, to which the zinc leading wire from the battery was connected, had a large patch of fusion near its base, and the front platinum contacts of the same (left-hand) pedal were consumed entirely. There were small traces of fusion on the right pedal, but of a trifling character. The line wire connected to the left-hand terminal of the key had been fused close to the terminal. The interior of the instrument case was considerably blackened, as also the greater portion of the keys, as a result of the "arc" caused by the discharge at the moment of fusion.

The vacuum protector at Ashintee, the base of the cable, also the plate protector in Fort William Post Office, were fused, but only slightly, the main discharge having expended itself on the summit. The Low Level Observatory instrument and protector were unimpaired, and communication between there and Fort William Post Office was carried on as usual after the removal of the fault in the Post Office protector.

The registering aneroid shows a slight upward kick at the time, but the curve is otherwise fairly steady; the temperature was 31·7 F., the wind south-south-east and light. Heavy snow was falling at the time, which, with a fall on the 17th, made a total depth of nine inches on the summit. St. Elmo's Fire was very strongly felt and heard until after seventeen hours.

WILLIAM S. BRUCE.

The Kinetic Theory of Gases.

IT seems to me that Mr. Burbury's and Prof. Boltzmann's last letters will enable us to reconcile all the *main* differences of opinion which were brought to light in our recent correspondence in the columns of NATURE. From Prof. Boltzmann's letter it appears that the Minimum Theorem can only be applied with absolute certainty to gases whose molecules are not too closely crowded together. Thus the proof that an aggregation of molecules tends *continuously* towards the Boltzmann-Maxwell distribution depends quite as much on assumptions as to the mixing of the molecules *between* collisions as on consideration of what happens *at* collisions. We cannot prove for certain that densely crowded assemblages of molecules such as solids and liquids tend to assume this distribution, and this is just as it should be, for when a substance is capable of existing simultaneously in two states, the distribution cannot be unique. For the same reason the proof does not apply to molecules moving about in a *continuous* medium such as the ether. So far from this limitation being a weak point in the proof, it precludes the theorem from proving too much, or from leading to results which may not accord with experience.

If we do not know that solids and liquids satisfy the Boltzmann-Maxwell distribution, we, nevertheless, know that they are subject to the Second Law of Thermodynamics. It cannot be said that any dynamical "proof of the Second Law" that has yet been given, is so conclusive as the mere statement of the Law itself, but the proof of the Minimum Theorem subject to "Condition (A)" leads to a result somewhat analogous to the statement that when two or more bodies at unequal temperature are brought into thermal contact, their entropy tends to increase. For let the probability of the coordinates on momenta of the molecules of one body lying between certain limits be proportional to F (*all* the coordinates and momenta being included in the multiple differential by which F is multiplied). Let the corresponding probability for a second body be proportional to f. Then when the two bodies are placed in thermal contact, we know of no relation connecting the two simultaneous probabilities, and we may therefore assume them to be independent, so that condition (A) is satisfied, at any rate initially. The theorem then asserts that at all subsequent instants of time, the value of the Minimum Function will be not greater than its initial value, and therefore it either remains stationary or decreases every time the process is repeated. Thus far we can get if no further.

The application of the Second Law depends largely on the distinction between *available* and *unavailable* energy. When we construct a thermodynamic engine for converting heat into work, we introduce just the kind of external disturbances that Mr. Burbury requires every time that the "working substance" is placed in contact with either the "source" or the refrigerator."

G. H. BRYAN.

An Abnormal Rose.

I HAVE in my garden at Reigate a *white* Moss rose-tree, every blossom on which is white except one which is half white and half red, divided diametrically in nearly equal portions.

The colours are not shaded one into the other, but are perfectly distinct, and one petal is half red and half white, the edge of the colouration being quite sharp.

I am told that one similar blossom was produced earlier in the season.

I imagine this is an attempt to revert to its ancestral colour, but by what mechanism such a partial result has been accomplished seems difficult to understand.

NEWNHAM BROWNE.

THERE are several varieties of rose that sport or revert in the manner described by Mr. Newnham Browne. The "York and Lancaster" rose is a familiar example. In this, the recognised or genuine condition is red and white striped; but the proportions of white and red are rarely exactly the same in any two flowers

on a bush, and very frequently some are wholly red and some, perhaps, wholly white, though I am not sure on this point. Many other cross-bred plants exhibit this inconstancy, which is supposed to be due to an imperfect blending of the elements of parentage. That the sporting is irregular and inconstant is not to be wondered at, when we consider that a plant is not an individual in the sense of possessing only one set of organs. Any vegetative bud of a plant is capable of producing any and all of the organs of the whole plant, or, if detached from the parent plant, to develop into a similar organism, with all its attributes. Given, then, a cross-bred variety, which is not constant, or "fixed," as florists term it, any vegetative bud may give rise to the cross or to one or the other of the parents.

W. Botting Hemsley.

Mineralised Diatoms.

Nearly twenty years have elapsed since you allowed me to announce in Nature the unexpected discovery of mineralised diatoms in the London clay of Sheppey.

Subsequent investigations demonstrated the existence of these unique microscopic fossils on the same geological horizon at several widely separated localities in the south-east of England; leading to the assumption that the band of diatomiferous earth was continuous throughout the formation.

Herne Bay was one of the places at which, in accordance with expectation, search was followed by success. Revisiting this place, a few days ago, for the first time since the discovery, I readily found the fossil diatoms as abundant as before in some recently fallen blocks of clay about half-way between Herne Bay and Oldhaven Gap. As there has been much waste of land at this spot during the interval, it is interesting to observe the presence of these diatoms in the newly exposed clay, giving support, as it does, to the hypothesis of their general distribution at a definite level throughout the London clay.

Perhaps some readers of Nature may be going to that part of the coast before long, and will then take the opportunity of verifying my observations.

W. H. Shrubsole.

SIR JOHN LUBBOCK AND THE TEACHING UNIVERSITY FOR LONDON.

THE address in which Sir John Lubbock solicits the suffrages of the Electors of the University of London has aroused feelings of surprise and regret among the friends of higher education in London, owing to the unfortunate nature of the references made to the Teaching University question. Six paragraphs out of ten are devoted to this important subject, and it seems almost incredible that so far from recognising that the Gresham Commissioners' scheme has enlisted a considerable measure of support in the University (*cf.* vol. l. 269; li. 298), Sir John Lubbock refers only to the views of its opponents, and, in accepting them, makes the remarkable statement:

"Feeling that Convocation ought to be consulted on a matter so vitally affecting the University, I would strongly urge, and do my best to secure, that the scheme when arranged should be submitted to Convocation for their approval, to be signified as at a Senatorial Election, and would oppose the Bill unless this were conceded."

Now it must be borne in mind that the Report of the Gresham Commissioners has met with a degree of approval from educational authorities and institutions, which not only far exceeds that extended to any previous attempt to solve the vexed question of University reform in London, but has been sufficiently unanimous to lead to the introduction of the "University of London Act, 1895," in the House of Lords by the late Government. This Bill, in accordance with the general tenour of the resolutions passed by the various institutions named in the Report as constituent colleges of the teaching University, enacted (clause iii. para. 1):

"The Commissioners will have power to make statutes and ordinances for the University of London in general accordance with the scheme of the Report hereinbefore referred to, but subject to any modifications which may appear to them expedient after considering any representations made to them by the Senate or Convocation of the University of London, or by any other body or persons affected."

And further (para. 2):

"In framing such statutes and ordinances, the Commissioners shall see that provision is made for securing adequately the interests of non-collegiate students."

Convocation in January last had the opportunity of exercising its veto in meeting assembled as provided by the Charter of the University on the scheme of reconstitution proposed by the Commissioners, which had previously received the general approval of the Senate. Instead of insisting on this right, it preferred to bring itself into line with the other institutions affected by the scheme, by adopting a resolution in terms almost identical with those employed in the Bill. Only so recently as May, it declined to reconsider this attitude by a majority of two to one, yet it is clear that the Bill, if again brought forward, is to meet with opposition from Sir John Lubbock, if re-elected, unless an amendment is inserted providing that the completed scheme shall be submitted to Convocation for approval in a manner expressly excluded under the terms of the present Charter, viz. by means of a referendum.

It is difficult to imagine by what process of reasoning this seemingly gratuitous proposal can be reconciled with the functions of a statutory, that is a judicial and executive, Commission. Convocation is but one of the bodies affected by the scheme, and in common with the others, it can, under the terms of the Bill, present its case for modifications in the scheme to the Commissioners before the statutes are framed, and like them can appeal against the statutes during the forty days they must lie on the table in both Houses of Parliament before they become operative. Such an amendment could only have the effect of wrecking the latest and most satisfactory scheme of University reform, since no other institution affected by the scheme could be expected to agree to such an unprecedented proposal. Nor is it likely that any person fitted to occupy the position would consent to serve on the Commission, and devote his time and best energies to the difficult and delicate work of adjusting the relations between these institutions, with the knowledge that the statutes and ordinances eventually framed would be subject to the approval of any irresponsible, non judicial body, let alone one of the institutions closely affected.

For the most part, Sir John Lubbock has held aloof from the controversy on the Teaching University question. Once only does he seem to have taken sides. It is on record that he voted with the majority when the Senate in June of last year passed a resolution expressing general approval of the proposals of the Gresham University Commission, with which action his present attitude is wholly inconsistent. It would be interesting to know whether his descent on the other side of the fence is in any way connected with the absence of opposition to his candidature on the part of the opponents of the scheme. Be this as it may, this uncalled for proposal to subordinate the interests of higher education in London to the pleasure of Convocation, ascertained not after debate, but by a referendum, is not to pass without protest, and we are glad to note that the following letters have already appeared in the press. The first is from Prof. Michael Foster, Sec.R.S., and President of Sir John Lubbock's Parliamentary Election Committee.

"Shelford, Cambridge, July 4, 1895.

"Dear Sir John,—As you know, I am wholly opposed to your view that the scheme for the University of London to be proposed by the Statutory Commissioners ought to be submitted to Convocation for approval. You also know that this difference of opinion, important as it is, does not prevent my desiring that you should continue to

represent the University of London in Parliament. I find, however, that your letter addressed to me is understood to show that I agree with all the opinions expressed by you in that letter, and in justice to myself I must make known to my fellow electors and others how wholly we disagree on the above point, and how much I regret the attitude you assume in the matters in question.

"Yours very truly,

"Sir John Lubbock, Bart." "M. FOSTER.

The second has been addressed to Sir John Lubbock by the President and a number of Fellows of the Royal Society:—

"July 6, 1895.

"Dear Sir John Lubbock, The interests of learning and of education are so closely bound up with the future development of the University of London that we hope you will not regard us as interfering between yourself and the Electing Body of the University if we venture to express our regret at some of the opinions you have put forward in your Election address.

"You state that you would do your best to secure that the scheme for the reorganisation of the University, when arranged, should be submitted to Convocation for their approval, to be signified as at a Senatorial Election, and would oppose the Bill unless this were conceded.

"You must allow us to point out that this proposal would confer upon Convocation a right, which is without precedent, to supervise the acts of a Commission entrusted with the reorganisation of the University of which Convocation itself is a part.

"The scheme of the 'Gresham Commissioners' has been approved not only by all the institutions concerned, but by the great body of educated public opinion. It is, however, certain that very grave difficulties will arise if the ultimate fate of the scheme is to depend upon the voting papers of Convocation.

"We, therefore, believe that the proposal you support, if adopted, will result in the failure of another attempt to establish a Teaching University in London, and will indefinitely postpone the solution of a question which, after prolonged discussion, seemed to be on the eve of settlement.

"We are, yours faithfully,

"KELVIN (P.R.S.), JOHN EVANS (Treas.R.S.), M. FOSTER (Sec.R.S.), JOSEPH LISTER, RAYLEIGH, DOUGLAS GALTON, T. G. BONNEY, T. E. THORPE, HORACE LAMB, J. H. POYNTING, ARTHUR W. RÜCKER, E. FRANKLAND, N. STORY MASKELYNE, HENRY E. ROSCOE, P. H. PYE-SMITH, J. NORMAN LOCKYER, JOHN ERIC ERICHSEN, WILLIAM RAMSAY, G. CAREY FOSTER."

In his address, Sir John Lubbock states that the opinions of the present Government on the University question have yet to be made known. In view of the fact that the Commission, whose report has been so generally approved, was appointed during Lord Salisbury's last term of office, this attitude ought not to be doubtful.

THE ELECTRICAL MEASUREMENT OF STARLIGHT.

THAT the light of a star is able to produce at the surface of the earth a measurable effect, other than the action on a photographic plate, is a fact which was published in these pages in January last year. The light of stars and planets produces two effects—the one photographic and the other electric. The first (which has, of course, been known for many years) is slow in its operation; the second (which was discovered only a year ago in Mr. Wilson's observatory at Daramona, Westmeath) is almost instantaneous.

In order to obtain the electrical effect, a photoelectric cell of extremely great sensitiveness to light is employed. Such a cell is constructed with selenium, aluminium, and the liquid œnanthol. If we take a strip of clean aluminium (say half an inch long, one-tenth of an inch wide, and thick enough to be fairly stiff) lay it on an iron plate which is heated by a Bunsen flame, and place on the end of the strip a very small particle of selenium, this selenium will melt and form a small black globule of liquid. Let the flame be now withdrawn, and the globule of melted selenium spread over the end of the aluminium strip, by means of a hot glass rod, so that it forms a thin uniform layer of area about ·1 of an inch square on the end of the strip, and let this dark layer cool to a few degrees below its melting point (about 217° C.). Now apply heat again to the under surface of the iron plate until the aluminium strip becomes nearly hot enough to re-melt the layer of selenium. In this process the colour of the layer will gradually change from black to a greyish brown. When it is just on the point of melting, withdraw the heat and blow over its surface; this will instantly check the tendency to melt, and will leave the surface of the selenium in the state in which it is most sensitive to light. If this strip (or rather its selenium-covered end) is immersed in a glass tube containing acetone or œnanthol, and connected with one pole of a quadrant electrometer, whose other pole is connected with a platinum wire sealed into the glass tube, we have a photoelectric cell, in which the action of light falling on the selenium layer results in giving the selenium a positive electric charge and the liquid a negative one, the former charge being conveyed to one pole of the electrometer by the aluminium plate, and the latter to the other pole by the platinum wire sealed into the cell.

Roughly speaking, the difference of potential produced in such a cell as this by ordinary diffused daylight is something between one-third and one-half of a volt.

Such were the seleno-aluminium cells used in the measurement of starlight in January 1894, the liquid in them being œnanthol. This liquid was found to be better than acetone (which had been previously used), not only because of the greater ease with which it can be sealed up in glass tubes, but because it does not act chemically on selenium, which acetone seems to do sooner or later. But it is obvious that a cell formed in this way contains an element of inconstancy; for, the strip of aluminium will at the same time convey to the insulated pole of the electrometer the positive charge generated by light in the selenium and a portion of the negative charge imparted to the liquid, so that the effective E.M.F. is less than it should be; and, again, there will be currents circulating perpetually between the selenium and the back of the aluminium strip, and such currents deteriorate the cell. Hence it happened that such cells always fell off in strength after about six hours. They sufficed, however, to show very easily measurable electromotive forces from the light of the planets, and even from the light of Sirius.

Shortly after January 1894, a very notable improvement was made in the construction of the cells, this improvement resulting from the perception of the cause of deterioration above explained. Instead of a strip of aluminium as a base for the selenium layer, the end of an aluminium wire, about one millimetre in diameter, was used. This wire was enclosed in a glass tube (A, B, in the figure on p. 247), into which it fitted tightly, one end of the wire being flush with an end of the tube. On this end was deposited the layer of selenium, with the same process of heating as that already described. The other end of the aluminium wire inside the glass tube was connected with a fine platinum wire, P, which emerged from the second end of the tube, and which formed the selenium pole of the photoelectric cell.

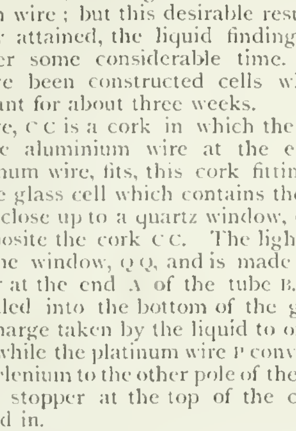
In this way the liquid is kept out of contact with the

aluminium wire, and the deteriorating local currents in the cell are avoided, if the glass tube *exactly* fits round the aluminium wire; but this desirable result has not yet been perfectly attained, the liquid finding its way into the tube after some considerable time. However, in this way have been constructed cells which have remained constant for about three weeks.

In the figure, C C is a cork in which the glass tube, B, containing the aluminium wire at the end A and the attached platinum wire, fits, this cork fitting tightly into the side of the glass cell which contains the liquid. The tube B passes close up to a quartz window, Q Q, cemented to the cell opposite the cork C C. The light of the star is received on the window, Q Q, and is made to fall on the selenium layer at the end A of the tube B. A platinum wire, P′, is sealed into the bottom of the glass cell, and conveys the charge taken by the liquid to one pole of the electrometer, while the platinum wire P conveys the charge taken by the selenium to the other pole of the electrometer; S is a ground stopper at the top of the cell, where the liquid is poured in.

This cell is fitted into a holder which can be fixed to a telescope in place of the eyepiece; and this cell-holder allows of the adjustments which are necessary to bring the point A to the position of the image of a star.

This is the form of photoelectric cell with which, in conjunction with Prof. Fitzgerald and Mr. W. E. Wilson, I measured the electromotive forces of the lights of



Jupiter, Saturn, Vega, Arcturus, Regulus, Procyon, and some other stars last April, in Mr. Wilson's observatory at Daramona, Westmeath. The telescope used was Mr. Wilson's 2-feet reflector.

In order to give a notion of the sensitiveness of the cell to light, I may say that if an ordinary paraffin candle is held at a distance of 9 feet from the window Q Q, it will produce an electromotive force of about ·03 volts; or, to put the matter differently, suppose an ordinary quadrant electrometer, of Clifton's pattern, charged so that a Daniell cell gives a deflection of 400 divisions on the ordinary scale (placed at a metre distance); then the light of the candle at 9 feet falling on the photoelectric cell would give a deflection of twelve divisions, and the deflection varies inversely as the distance of the candle.

Now the light of Vega as concentrated in the 2-feet telescope gives a slightly greater deflection than the (of course unconcentrated) light of the candle; so that we are evidently dealing with easily measurable quantities.

The cell is sensitive to all the rays of the spectrum, but the maximum effect is produced by the yellow. It is sensitive to rays considerably below the visible red and beyond the blue.

The light of Arcturus was found to give 0·82 of the E.M.F. produced by the candle at 9 feet; the light of Saturn 0·56, which was also about the value of the light of Regulus. Unfortunately neither Sirius nor Capella, nor any star in Orion, nor any in the Great Bear, was available for our observations; but these we hope to include, before long, in the list of measured stars.

It will be observed that in this electrical measurement of starlight we do not measure *currents*, but *electromotive forces*—we do not use a galvanometer, but an electrometer; and an electrometer of small capacity was specially constructed for these experiments, with the aid of the Government grant dispensed by the Royal Society.

It is not desirable to allow the light to generate *currents*: the electrical charges must be allowed to flow back into the cell, so that it may not be temporarily deteriorated during the observations. Hence the preference for the electrometer.

The space at my disposal will not allow of my entering into many details; but I may mention, in particular, the importance of having the whole of the sensitive surface in the cell covered by the light of the star. It matters not to the value of the E.M.F. produced how far behind the focal image of the star the sensitive surface, A, is placed—provided that the image of the star just covers the surface A. This is essential in all photoelectric cells, and also in thermopiles; and the neglect of this condition may partly explain the failure of attempts to obtain thermoelectric indications from the stars and planets, although we should scarcely expect success from methods which aim at measuring merely a very limited portion of the radiation (viz. the heat, or infra-red). The photoelectric cell integrates the whole energy of the radiation on the sensitive surface; and the *square* of the observed E.M.F. is the measure of this incident energy.

It is interesting to know how the *photelectric* measures, so far as they have gone, compare with the *photometric* measures of "magnitudes" hitherto employed by astronomers. In the latter, if B and B′ are the "brightnesses" of two stars of the magnitudes m and m' respectively, we have by definition

$$\log_{10}\frac{B}{B'} = \frac{4}{10}(m' - m), \quad \ldots \ldots \quad (1)$$

This equation defines merely the difference of the magnitudes, and the definition is quite arbitrary. The essential things are B and B′. How are they measured? The photoelectric method says that they are E^2 and E'^2, the squares of the electromotive forces generated in a given cell by the lights of the two stars. The photometric method says that they are measured by the thicknesses of certain interposed glass prisms which extinguish the lights, or by polarising apparatus which render the shades of the transmitted lights "equal." Hence we may expect, perhaps, a fair amount of agreement between the two methods, if we are comparing two or more stars of the same colour. Thus, in the photoelectric method, we have for any two stars

$$m' - m = 5\log_{10}\frac{E}{E'}, \quad \ldots \ldots \quad (2)$$

Applying this to Arcturus and Regulus, and taking the magnitude of the former as ·2, we find the magnitude of Regulus to be 1·33. In Miss Clerke's "System of the Stars" (Appendix), Regulus is quoted as 1·4, Arcturus being ·2.

Comparing in the same way Procyon and Regulus, the latter being taken as of magnitude 1·33, the magnitude of Procyon would be ·46. Miss Clerke quotes Procyon as of magnitude ·5.

But no agreement between the two methods is to be expected when two stars of different colours are compared. The photometric method of equalisation seems to be just as meaningless as the ordinary "grease-spot" method of attempting to equalise a blue and a red light! In this case the only intelligible comparison of two lights consists in measuring the energies which they radiate per

unit time per unit area at a given distance—just, for example, as Newton's Second Axiom defines two masses to be "equal" when the same force produces the same acceleration in both; an equality which is *real* if the substratum at the basis of all bodies is the same, but merely *conventional* if it is not.

If the distance of a star is known, we can determine its intrinsic energy, *i.e.* the quantity of energy which it radiates into all space per unit time.

Thus, let I be the intrinsic energy of a star whose distance from the earth is R; let E be the electromotive force of its light as measured by the cell; let i, r, e be the analogous quantities for a candle or any other chosen source of light; and let A and a be the areas of the aperture of the telescope and the selenium surface in the cell. Then we have

$$\frac{I}{i} = \frac{R^2 . E^2 . a}{r^2 . e^2 . A} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Let us take, for example, a result which Prof. Boys recently told me that he had obtained. He found, in conjunction with Mr. Watson, of South Kensington, that if the light of a standard candle was observed across a valley and almost in the line of sight of Arcturus, the light of the candle and that of the star seemed to be equal when the candle was at a distance of five-eighths, or ·625, of a mile.

Now, let x be the distance at which the candle light seems to be as bright as that of the star. Then

$$\frac{I}{R^2} = \frac{i}{x^2}; \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

And if D and d are the diameters of the telescope aperture and the circular layer of selenium in the cell, we have from (3)

$$x = r\frac{e . D}{E . d} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

Put, now, $r = 9$ feet, $e = 10$, $E = 8·2$, $D = 24 \times 25$ millimetres, $d = 2$ m.m., as in our experiments, and we find

$$x = 3300 \text{ feet, nearly}$$
$$= ·62 \text{ miles.}$$

This agrees remarkably well with the observation of Prof. Boys. George M. Minchin.

FUNERAL OF PROFESSOR HUXLEY.

In accordance with his own wish, the late Prof. Huxley was buried at the Marylebone Cemetery, Finchley, last Thursday afternoon. The coffin came up from Eastbourne in the morning, and the numerous mourners assembled at the cemetery to meet it. Wreaths from members of the family, and from friends and fellow workers of the great naturalist whose loss we mourn, covered the coffin. The Royal College of Science, with which Huxley was connected so many years, sent a large wreath, and there were also wreaths from Lady Hooker, Mrs. Tyndall, the members of the staff at the Royal Gardens, Kew, Mr. Herbert Spencer, Sir Henry Thompson, Sir Henry Roscoe, Messrs. Macmillan, and the Editor of Nature, among others.

The funeral service was performed by the Rev. J. Llewelyn Davies, an old friend of Prof. Huxley's, now rector of Kirby Lonsdale, but formerly vicar of Marylebone, where he was for a long time Huxley's neighbour.

The family was represented by Mrs. Huxley, the two sons, Mr. Leonard Huxley and Mr. Henry Huxley, and three daughters, the Hon. Mrs. Collier, Mrs. Waller, and Mrs. Eckersley (the remaining daughter, Mrs. Roller, is in Switzerland with her husband, who is ill), Mrs. Heath (a niece), and two sons-in-law, the Hon. John Collier and Mr. I. W. Waller.

No announcements of the funeral were sent out, and the large number of distinguished men who attended, and the various learned Societies that sent representatives, did so on their own initiative. The Royal Society was officially represented by Lord Kelvin, Sir John Evans, Prof. Michael Foster, and Sir J. Lister, many of the Fellows also being present. The Geological Society was represented by Dr. Henry Woodward, Dr. Blanford, and Prof. Bonney. Dr. Frankland, Mr. Crookes, Dr. Thorpe, and Dr. Gladstone were the representatives of the Chemical Society. The mourners from the Royal College of Science included Prof. Rucker, Prof. Norman Lockyer, C.B., Prof. Tilden, Prof. Judd, C.B., Prof. W. C. Roberts-Austen, C.B., Prof. Howes, Prof. Farmer, Dr. Wynne, Mr. J. W. Rodger, and Mr. Woodward. Major-General Sir J. F. D. Donnelly, K.C.B., Major-General Festing, Captain Abney, C.B., Mr. T. Armstrong, Mr. F. R. Fowke, and Mr. A. S. Cole represented the Science and Art Department; Sir William Flower, K.C.B., Dr. A. Gunther, Mr. George Murray, Mr. C. E. Fagan, Prof. Jeffrey Bell, and Mr. F. A. Bather, the Natural History Museum; Prof. Armstrong, Prof. S. P. Thompson, Prof. Perry, and Prof. Ayrton, the City and Guilds Institute; Mr. Stanley Boyd, Mr. H. F. Waterhouse, Mr. J. F. Pink, the Charing Cross Hospital Medical School; Mr. J. J. H. Teall, Mr. F. W. Rudler, and Mr. E. T. Newton, the Geological Survey. In addition to the Fellows of the Royal Society not included in the above, there were present Prof. E. Ray Lankester, Dr. Dallinger, Sir Joseph Hooker, K.C.B., General Strachey, Dr. Lauder Brunton, Dr. Sclater, Prof. Carey Foster, Prof. G. H. Darwin, Sir James Paget, Dr. Burney Yeo, Prof. H. Marshall Ward, Prof. Seeley, and Mr. F. Darwin. Among the other mourners were Mr. Walter Troughton, representing Mr. Herbert Spencer, who was prevented by illness from being present, Dr. T. K. Rose, Mr. W. Darwin, Mr. A. H. Heath, Mr. S. Highley, Mr. W. S. Stewart, Major-General Sir Richard Pollock and Mr. D. Pollock, Mr. Alma Tadema, Mr. W. E. H. Lecky, Mr. and Mrs. Humphry Ward, Mrs. Tyndall, Mrs. W. K. Clifford, Mr. Henry James, Mr. Mark Judge, Mr. H. Saunders, Dr. Semon, Mr. F. Macmillan, Mr. G. L. Craik, Mr. Clodd, Mr. G. Griffith, Lady Staveley Hill, Mr. Paynter Allen, Mr. John Boyes, Mr. Spencer Walpole, Mr. Woodd Smith, Dr. J. Johnson, Mr. James Hulme, Mr. Stanley Edwards, Dr. Glover, Mr. T. B. Windsor, the Rev. D. D. Jeremy, Dr. J. Malecki, Mr. J. Spiller and Mr. and Mrs. Briton Rivière.

The funeral was at first announced to take place at 3 o'clock, whereas the time fixed upon was 2·30. Owing to a delay in the train, a number of workers in science, from the Midlands and the North of England, did not arrive at the cemetery until the ceremony was over, and thus, to their deep regret, they were deprived of the melancholy satisfaction of being present when the remains of an esteemed master and friend were laid to rest.

The memory of Huxley will always be cherished among men of science, and it is imperative that there should be a permanent memorial of some kind to show the world how great is their regard for him. The memorial should be a truly national one, and not limited to any particular institution. We understand that the Dean of Westminster is willing that a tablet shall be erected in the Abbey if desired, and this is one of the forms which the memorial might take. Sir William Flower suggests another form, in a letter to the *Times* of Monday. He writes:

"In the great hall of our national Museum of Natural History the noble statue of Darwin will hand down to posterity the image of the man as he appeared to all who knew him in life. Near this will soon be placed another statue remarkable for the accuracy with which the striking personality of Owen is represented, as all who see it now at the Royal Academy Exhibition can testify.

Surely this group of the great naturalists of this country and this century must be completed by the one we have just lost, in some respects the greatest of the three. The statues of Pitt and Fox stand side by side in Westminster Abbey. Huxley and Owen, often divided in their lives, would here come together after death in the most appropriate place and amid the most appropriate surroundings."

What is now wanted is a representative committee to take the matter up; we are confident that an appeal for funds would meet with a ready response, and we are glad to know that steps are being taken in this direction. A circular signed by Dr. Foster and Sir William Flower has been issued, calling a meeting at the rooms of the Royal Society this afternoon.

NOTES.

THE meeting at which the Prince of Wales presided in St. James's Palace on Tuesday, ought to further the interests of the British School at Athens, in support of which it was held. A distinguished and representative company was present, among them being many well-known men of science. The Prince of Wales has concerned himself with the existence and welfare of the School from the time of its foundation in 1883, and we are glad to notice that in his remarks to the meeting he drew attention to the fact that the scantiness of the means provided was out of all proportion to the valuable archæological work carried on. The School only has a precarious annual income of £500, whereas the French School at Athens has an assured income of over £3000 a year, and the German School more than £2000 a year. Owing to this state of affairs, it is quite impossible for the British School to enter into competition with such undertakings as the explorations of the Germans at Olympia, the French at Delphi, the Americans at Argos, or the Greeks at Eleusis and Epidaurus. The sum required to bring England approximately into line with other nations is at least £1500 a year. Fortunately, as the Prince of Wales remarked at the meeting, there are hopeful signs that matters will soon be placed on a more satisfactory footing. A petition for support addressed to the late Government, met with a ready response; and before leaving office Sir William Harcourt took steps to use some portion of the public funds devoted to the encouragement of scientific investigation for the support of the School, and it is understood that the present Ministers are willing to confirm the action of their predecessors. One of the colleges at Cambridge, which has been most severely tried through the agricultural depression, has generously made an annual appropriation out of its reduced funds, and three colleges at Oxford have voted annual grants. The public schools are also moving in the matter. The Prince of Wales suggested that perhaps some of our City Companies, whose funds are devoted not only to local charities, but which have extended their sphere to the support of educational and scientific institutions, may see their way to encourage research in Greece; and he hoped that our colonies, which are so intimately bound up with our own culture and our higher national aspirations, will recognise the fact that all the privileges of the Athens School are open to their qualified students, and will make some effort towards securing its adequate efficiency. Lastly, he appealed to the liberality of private individuals, and expressed himself convinced that the appeal would find a response throughout the country. Every year excavation, both in Greece and elsewhere, is becoming more important to science. The following resolutions, confirmatory of the object of the meeting, were carried unanimously:—(1) "That the British School at Athens has already done excellent work during the nine years of its existence, and is well deserving of increased support." (2) "That this meeting pledges itself to use every effort to place the School upon a sound financial basis, so that in point of dignity and efficiency it may worthily represent this country among the other foreign institutes in Athens."

PROF. CURTIUS, of the University at Kiel, has been appointed successor to the late Prof. Lothair von Meyer at Tübingen.

PROF. DANIEL C. EATON, well known in botanical circles by his work on ferns, has just died at New Haven, U.S.

WE learn that M. J. Deby, one of the leading authorities on diatoms, whose magnificent collection was recently acquired by the British Museum, is dead. He was in his seventieth year, having been born at Lacken, in Belgium, in 1826.

To the list of honours given last week should have been added Sir Bernhard Samuelson, M.P., F.R.S., who has been made a Privy Councillor, and Dr. H. D. Littlejohn, who has been made a knight. On Thursday last, Mr. Thornley Stoker, President of the Royal College of Surgeons in Ireland, and Dr. Christopher Nixon, were knighted by the Lord-Lieutenant of Ireland.

THE date of the annual meeting of the Society of Chemical Industry, which is this year to be held in Leeds, has been postponed from July 17 to July 31, in consequence of the General Election. It is not thought that any material change will have to be made in the programme.

PROF. SCHWARZ has been elected a Correspondant of the Paris Academy, in the Section of Geometry; Baron von Müller has been elected to the late Prof. Pringsheim's place in the Section of Botany, and Prof. Engelmann succeeds Ludwig in the Section of Medicine and Surgery.

WE are glad to be able to announce that the Italian Meteorological Society, which was temporarily dissolved after the death of Padre Denza, has again been reorganised, under the presidency of Count Vigodarzere, who is the proprietor of an observatory at Fontaniva. The central observatory will be at Moncalieri, as before, and we look forward to a continuation of the useful work carried on formerly by the Society.

WE are informed that King's College, London, will open next October a department for training teachers for Secondary Schools. There will be a two-years' course of technical studies combined with the preparation for the B.A. degree of the University of London. Detailed instruction in the art of teaching particular subjects will be given by the Professors of the College. Six Exhibitions of £15 are offered. Names of students should be sent in before September 16.

A REUTER correspondent at St. John's reports that the steamer *Kite* left there for Greenland on Tuesday to bring home the Peary Arctic Expedition. It is expected to return on October 1. The party on board includes Prof. Salisbury, of Chicago University, who goes to study the glaciers and geology of the region; Prof. Dyche, of the State University, Kansas, who will collect specimens of the fauna and flora; and Mr. Boutillier, of Philadelphia, who represents the Geographical Society.

THE influence of the Royal Gardens at Kew is felt in widely different regions of the world, through the men who are trained at the Gardens and sent out to various Botanic Stations. Three new appointments of men who have benefited by the Kew training, are notified in the current Kew *Bulletin*: they are Mr. C. H. Humphries, who has been made Curator of the Botanic Station of Aburi, on the Gold Coast; Mr. J. C. Moore, who has been appointed Curator of the Botanic Station at St. Lucia, in the Windward Islands, West Indies; and Mr. H. McMillan, who goes as Head Gardener to the Royal Botanic Gardens at Peradeniya, Ceylon.

MR. A. B. BASSET has sent us a letter referring to the proposed changes in the size of the pages of the Royal Society's publications. He directs attention to chapter xii. section ii. of the Statutes

of the Society, empowering any six Fellows to convene a special general meeting, and suggests that such a meeting should be summoned, and the following resolutions submitted to it: (1) That this meeting is of opinion that the present form of publishing the *Transactions* should be continued. (2) That this meeting is of opinion that the present form of publishing the *Proceedings* should be continued. The resolutions are drawn up separately, so as to obtain the votes of Fellows who approve of a change being made in the form of one kind of publication, but disapprove of any change as regards the other.

IN the recent death of Prof. Verneuil, France has lost one of her most eminent surgeons. His name is intimately connected with the history of contemporary surgery. At first, Assistant of Anatomy, Prosector, as well as Professor of Anatomy to the Faculty of Medicine, he devoted himself to anatomical and physiological studies, and left his mark by important works, chiefly on the heart, and on the anatomy and physiology of the venous system. Later, he formed part of that noted phalanx which, under the auspices of Lebert, with Robin, Broca, Follin, introduced histological studies into France. From this time date a series of original memoirs, notably on the demoid cysts of the face, and on the scrotal enclosure, in which he expounded new views, and established the scientific theory which is now generally adopted. Later still, when hospital surgeon and professor in the Faculty of Medicine, he introduced important methods of operation. Animated by the most ardent love of science, he knew how to communicate his enthusiasm to those around him; he had all the requisite qualities of a founder of a school. His activity showed itself by a great number of communications to learned societies of which he was a member.

THE extensive science laboratories and buildings recently opened at Lille are described in detail in the *Revue Générale des Sciences*. The buildings comprise a physical institute, an institute of natural science, and an institute of chemistry, erected at a cost of £65,000. The cost of the whole work was nearly £140,000, and this has been borne by the Municipal Council and the Academy at Lille, assisted by a gift of £4000 from M. Philippart. The town of Lille has guaranteed an annual grant of £800 for twenty years, to be used in the interests of higher education, and has shown the greatest interest in the work of the new institute. The department of chemistry is divided into two parts, in which general chemistry and applied chemistry are respectively dealt with; and in each section laboratories are provided for research as well as for instruction. The physical department occupies a separate building, in which accommodation is provided for experiments of extreme delicacy as well as routine work. On account of the great stability now demanded by many physical investigations, all the research laboratories are on the ground floor; for the same reason, numerous large isolated pillars of masonry have been provided, and strong slate slabs have been fixed into the corners of the laboratories. The natural science building provides accommodation for geology, zoology, and botany; and a room is reserved for the Geological Society of the North of France. Every facility for study under good conditions appears to be offered by the new laboratories, and higher education in France will derive benefit from the increased opportunities now offered it at Lille.

THE Third International Agricultural Congress will take place at Brussels from September 8 to 16; hence it will clash with the meeting of the British Association at Ipswich, which begins on September 11. The Congress will be held under the patronage of the King of the Belgians, and embraces twelve sections. In the section of agricultural education the subjects for discussion include rural schools, fields for experiment and demonstration, the possibility of devising an international programme of superior agricultural study, and the professional training of farmers' sons by interchange of the young people of different districts. The section of agricultural science will embrace chemistry and physiology as applied to agriculture; the utilisation and conservation of natural manures; agricultural meteorology; experiment stations and laboratories of control for manures, foods, and seeds. The third, fourth, and fifth sections deal respectively with co-operation, legislation, and currency. The section of animal production will discuss practical questions relating to stock-breeding, selection and crossing, the improvement of breeds, and the feeding of stock in times of drought. The veterinary section will concern itself with the organisation of veterinary sanitary police and the contagious diseases of animals, including pleuro-pneumonia, anthrax, and tuberculosis. The section of plant production is to discuss the selection of seed, the cultivation of malting barley, "sidération," the cultivation of peaty and mossy soils, drainage, and irrigation. The ninth section—southern agriculture and colonisation—embraces grape and silk culture; the cultivation of flowers for perfume, of oil-yielding plants, and of coffee, tea, and sugar-cane; the agriculture of the Congo and of Tunis; and the conditions of countries to which emigrants might be sent. The tenth section takes in forest economy, the eleventh deals with pisciculture, and the twelfth with agricultural industries, such as dairying, brewing, and bee and poultry culture.

THE results of a competition organised at Paris last month, by the *Petit Journal*, are of some scientific interest. Sixty thousand carrier pigeons from all parts of France, and from some places in Belgium, were released from the Eiffel Tower at known intervals and times. The first pigeon travelled a distance of 150 kilometres ($93\frac{1}{4}$ miles), with a velocity of 76 kilometres (47 miles) per hour. The highest average rates of flight ranged between this and 43 miles per hour for a distance of 264 miles. These rates are low compared with previous records. A distance of 600 miles has been covered at an average rate of 50 miles an hour, and in June 1860, a pigeon travelled from Blois to Dijon, a distance of 290 miles, in 4h. 46m., which gives a rate of about 60 miles per hour. There is also evidence that much higher average velocities than these have been reached.

DR. J. HANN, Secretary of the Vienna Academy of Sciences, laid before it, on the 20th ult., an investigation on the daily range of the barometer on clear and cloudy days, especially on mountain summits. It was known that at ordinary stations the daily barometric range in clear and cloudy weather only exhibited a difference in the single daily oscillation, while the double daily oscillation remained unchanged. But a similar investigation for mountain stations had not yet been made. With this object the author undertook the tedious operation of calculating the daily barometric range at a number of mountain stations for the summer season, and found that at these the double daily oscillation remained the same in both kinds of weather. At the earth's surface the daily curve showed a much greater amplitude in clear than in cloudy weather, and a totally different epoch. The average form of the daily curve for the mountain stations is represented by the formula: $0.48 \sin (353^{\circ} + x)$ on clear days, and $0.26 \sin (101^{\circ} + x)$ on cloudy days. On clear days the maximum of the single daily oscillation occurs at 6h. 30m. a.m., while on cloudy days it occurs at 11h. p.m. The author also found that the differences in the daily range on clear and cloudy days corresponded entirely to the differences which exist over the land, as compared with those over adjacent seas.

A RETURN has been issued showing the number of licensed experiments performed on living animals during 1894. The total number of persons holding licences during the year was 185, and of these 56 performed no experiments. The tables given afford evidence that licences and certificates have been granted and allowed only upon the recommendation of persons

of high scientific standing, and that the licencees are persons who, by their training and education, are fitted to undertake experimental work and to profit by it. All the experimental work has been conducted in suitable places: the number of experiments performed was 3104. In more than one-third of these the animal suffered no pain, because complete anæsthesia was maintained from before the commencement of the experiment until the animal was killed. More than fifteen hundred of the remaining experiments were of the nature of hypodermic injections or inoculations. In about five hundred experiments the animal was anæsthetised during the operation, but was allowed to recover. These operations, in order to insure success, are necessarily done with as much care as are similar operations upon the human subject; and the wounds being dressed antiseptically, no pain results during the healing process.

The Geologists' Association will visit the coast of Antrim and the Mourne Mountains this summer (July 29 to August 3). The programme includes the examination of sections in sedimentary rocks ranging from the Ordovician to the Chalk, pre-Devonian gneisses, and the basalts, rhyolites, and drusy granites of the Tertiary eruptive series. The illustrative papers by Messrs. McHenry and Lloyd Praeger will shortly be issued as a pamphlet, in advance of publication in the *Proceedings*. The country to be visited is classic, and additional interest is added to it by the recent publication of two papers in the *Geological Magazine*. The first of these, in the June number, by Mr. McHenry of the Irish Geological Survey, describes valuable evidence as to the age of the trachyte (rhyolite) of the district. In a section at Templepatrick Quarry, the acid lava is seen, by the arrangement of its columnar and flow-structure, to have flowed over the surface of the Chalk, sweeping the overlying gravel before it, and piling it up against the denuded edge of a mass of basalt belonging to the *earlier* of the two basic series. As fragments of the trachyte occur elsewhere in gravels overlain by the *later* basalts, it may be said to be of "mid-basaltic" age. The second paper, in the July number, is by Prof. Cole, and deals with the nature of the acid rocks poured out from the Tardree volcano, which are said to equal in variety the better known rhyolites of Hungary.

The numbers of the *Botanical Gazette* for May and June contain a translation, by Mr. G. J. Peirce, of Prof. Strasburger's paper on the "Development of Botany in Germany during the Nineteenth Century." In the latter number there is also a very instructive article, by Mr. J. M. Coulter, on the "Botanical Work of the American Government." At present four distinct divisions of botanical work are organised under the Department of Agriculture, although other divisions also do a certain amount of work that may fairly be called botanical. These four divisions are those of botany, vegetable physiology, and pathology, agrostology, and forestry. The Division of Botany, under the general supervision of Prof. F. V. Coville, of Cornell University, is engaged in strictly scientific work, such as the working out of local floras, the examination of seeds, investigation of weeds, &c. To this department the Government appropriates, during the present year, 33,800 dollars. The division of vegetable physiology and pathology (26,300 dollars) is concerned with investigations into the phenomena of the growth of plants, and into the diseases of cultivated plants. Its chief is Prof. B. T. Galloway, University of Missouri: but investigations on behalf of the department are carried on also at the following centres:—University of Nebraska, University of Michigan, University of Illinois, Kansas Agricultural College, University of Copenhagen. The function of the Division of Agrostology (15,000 dollars) is to deal with forage plants as well as grasses, to instruct and familiarise the people with the habits and uses of these plants, to conduct investigations relative to their natural history and adaptability to different soils and climates, to introduce promising native and foreign plants into cultivation, and to identify grasses and forage plants. Its chief is Prof. F. Lawson-Scribner. The Division of Forestry, under the charge of Mr. B. E. Fernow, has at present chiefly been occupied with the study of character and value of different timbers.

The current number of the *Journal de Physique* contains the second part of the paper, by M. P. Curie, on the magnetic properties of bodies at different temperatures (see Nature, June 6, 1895, p. 134). The present paper deals with iron, nickel, and magnetite. In the case of iron, measurements have been made at temperatures between 20° C. and 1360° C., and for field strength of from 25 to 1350 C.G.S. units. The observations on nickel and magnetite were only made at temperatures above that at which the great change in the magnetic properties of these bodies takes place. The values obtained with iron up to about 756° C. agree with those previously obtained by Dr. Hopkinson. Above this temperature the author finds that the curves showing the relation between the intensity of magnetisation (I) and the strength of the field are straight lines passing through the origin for temperatures between 750° and 1280° F. decreases more and more slowly. At first (I) decreases to half its value for a rise of temperature of a few degrees, but between 950° and 1280° the susceptibility is almost a constant, only decreasing very little as the temperature rises. At a temperature of about 1280 the susceptibility suddenly increases by about 50 per cent., and then again gradually decreases up to 1365°. The author, with some hesitation, gives the following explanation of this behaviour: "Up to a temperature of 860° iron behaves like any other paramagnetic body. At a temperature of about 860°, however, it begins to change into a second allotropic form, this transformation being complete at about 920°, and the iron remaining in this condition up to 1280°, and behaving like such a body as oxygen or palladium. Finally at 1280° the iron changes suddenly back to its first condition." The attractiveness of the above theory can only be appreciated by a study of the author's curves, for if the curve showing the connection between the logarithm of the susceptibility and the logarithm of the temperature is plotted, it is found that the curve between 750° and 860° would, if prolonged, form with the curve above 1280° a curve in all respects similar to the curves obtained in the case of nickel and magnetite. With nickel the author finds that the temperature of the magnetic transformation is about 340°. After this temperature the susceptibility is independent of the strength of the field, and decreases regularly and very rapidly as the temperature rises. In the case of magnetite the chief magnetic transformation takes place at a temperature of 535°. At temperatures between 550° and 1370° the susceptibility is independent of the strength of the field, and decreases regularly, and between 850° and 1360° varies inversely as the absolute temperature. The value of K (see previous note, *loc. cit.*) being given by the expression $K = \frac{0 \cdot 0280}{T}$ where T is the absolute temperature. From the differences exhibited by the behaviour with change of temperature of diamagnetic and paramagnetic bodies, the author considers that these two properties must be attributed to different causes.

Last week the *Pharmaceutical Journal* began the first of a new and enlarged series (the fourth). The journal, which is now in its fifty-fifth year, has done much to promote pharmaceutical organisation and progress.

The second part of the Report of the International Meteorological Congress held at Chicago in 1893, has just come to us from the United States Department of Agriculture (Weather Bureau). The papers included in the Report were communicated

to the sections of history and bibliography, agricultural meteorology, and atmospheric electricity and terrestrial magnetism. Part iii. will comprise climatology, instruments and methods of observation, and theoretical meteorology.

THE most important articles in the *Kew Bulletin* for April to July, are one on the various sugar-cane diseases in Barbadoes, one on maple sugar, containing information with regard to the growth of the sugar-maple in the United States; and one on anbury, club-root, or finger-and-toe, describing the mode in which this disease is produced in a number of species of Cruciferæ by the attacks of the parasite *Plasmodiophora Brassicæ*, and the best modes of counteracting it.

THE new quarterly number of the *Journal* of the Royal Agricultural Society contains a paper on "Cross-bred Sheep," by Mr. H. J. Elwes, in which many facts of biological interest are recorded. The value of a first cross between two pure breeds is insisted upon, whilst due importance is attached to the dangers which beset the breeder should he venture beyond the first cross. Mr. Elwes is in a position to draw upon the results of long practical experience in the cross-breeding of sheep. The general improvement which the sheep of this country have undergone within recent years is attributed to the increasing resort to the services of pure-bred sires, but much remains to be done by those breeders who possess the necessary skill, patience, and energy. Another paper of scientific interest is one by Prof. G. T. Brown, C.B., on "Ringworm of Calves," which is illustrated with five original drawings. It is demonstrated that the living spores of the fungus of ringworm may be transmitted from one animal to another by means of lice. Prof. Edgar M. Crookshank contributes a popular paper on "Microbes in Health and Disease," and economic botanists will find much that is interesting in Mr. Glenny's paper on "The Onion and its Cultivation." This issue also contains a schedule of such native wild birds as are "undoubtedly beneficial to agriculture." Altogether, 38 species are enumerated, and details are given concerning their food, nests, and eggs.

THE additions to the Zoological Society's Gardens during the past week include an Anubis Baboon (*Cynocephalus anubis*, ♂), a Leopard (*Felis pardus*), two Two-spotted Paradoxures (*Nandinia binotata*), a Sharpe's Wood Owl (*Syrnium nuchale*) from Accra, Gold Coast, presented by Mr. W. H. Adams; two Red-crested Cardinals (*Paroaria cucullata*) from South America, presented by Dr. G. Fielding Blandford; a Small Hill Mynah (*Gracula religiosa*) from India, presented by Mr. W. Norbury; a Brown Capuchin (*Cebus fatuellus*) from Brazil, presented by Mr. W. L. Gibbs; a Spiny-tailed Monitor (*Varanus acanthurus*) from Roebuck Bay, West Australia, presented by Mr. Saville Kent; a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, an Egyptian Uromastix (*Uromastix spinipes*) from Egypt, deposited; two Mantchurian Cranes (*Grus viridirostris*) from North China, purchased; two Mule Deer (*Cervus macrotis*), a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

SPECTRA OF PERIODIC VARIABLE STARS.—The recent spectroscopic observations of δ Cephei by Belopolsky (NATURE, vol. li. p. 282), and of β Lyræ by Pickering, Lockyer, and others, have shown that we have still a great deal to learn as to the causes of the light-changes in variables of short period other than those of the Algol type. In these inquiries, it has become clear that a study of the light-curves must go hand-in-hand with that of the spectroscopic changes, and we therefore welcome the publication, by Dr. Schur, of new light-curves of δ Cephei, η Aquilæ, and β Lyræ (*Ast. Nach.* 3282–83). The observations were made at Strassburg in the years 1877–85 by Argelander's method, an opera-glass providing the requisite optical aid.

In the case of δ Cephei, the observations and light-curve agree very well on the whole with those of Argelander and Schonfeld, but the interval from minimum to maximum is reduced by Dr. Schur from 1d. 14·6h. to 1d. 13·7h., and the period derived is 5d. 8h. 47m. 38·047s., or 1·027s. less than that of Argelander. There does not seem to be any ground for the idea that the length of the period is sensibly changing. Dr. Schur also obtained distinct evidence of a standstill in the light-curve in the descent to minimum. The period arrived at for η Aquilæ is about 4s. less than that of Argelander, namely, 7d. 4h. 13m. 59·318s. A very decided "hump" is shown on the descending side of the light-curve: this is not merely a halt like that in the case of δ Cephei, but an actual increase of light, commencing about 3d. 20h. after minimum, and reaching an abortive maximum about twelve hours later. The interval from minimum to maximum is 2d. 6h. The observations of β Lyræ give a light-curve of which the general form is almost identical with that given by Argelander, but the agreement of individual minimum with calculated times is not very good. To bring these into better agreement, Argelander's formula is corrected to the following: Epoch 424, Bonn mean time, 1855 Jan. 6, 15h. 28m. + 12d. 21h. 47m. 23s.·72 E + 0s. 315938 E² − 0·0000121 1s. E³.

The paper gives full details of the observations and their reduction, and its value is increased by a plate showing the forms of the light-curves of the three variables in question.

THE NICE OBSERVATORY.—Vol. iv. of the *Annales* of the Nice Observatory is a monument to the industry of the director and staff of the magnificent observatory founded by M. Bischoffsheim. M. Perrotin, the director, contributes an elaborate investigation of the inequalities of the first order in the elements of Vesta, produced by the action of Jupiter, employing interpolation methods. M. Javelle furnishes full particulars of 505 new nebulæ discovered by him during 1890 and 1891 with the great equatorial of 15 inches aperture. The positions of these were determined by micrometric measures of distances from comparison stars, and awaiting accurate meridian observations of these, provisional positions for 1890 have been computed. Some of these objects are easily visible, but the majority of them are rather difficult, and others are at the limit of visibility of the Nice refractor. Star clusters have been rigorously excluded from the catalogue.

The meridian work at the observatory is particularly directed to the double stars of the Dorpat catalogue, and the already numerous stars which have been used as comparisons in the observations made with the equatorial. The period covered by the present publication is 1888 April 5 to 1889 December 23.

From May 1887 to December 1892, 26 new minor planets were discovered at Nice by M. Charlois, the last 11 by photography. A vast number of observations of these and other minor planets have also been made by M. Charlois, full details of which are recorded in the present volume. Observations of 10 comets are also included.

FOUCAULT'S PENDULUM EXPERIMENT.—The experimental demonstration of the earth's rotation, devised by Foucault in 1851, has recently been repeated at the De La Salle Training College, Waterford, on a somewhat smaller scale than in the original experiment. The weight of the pendulum bob was 19 lbs., and it was suspended by a wire 37 feet 6 inches in length. To set the pendulum in vibration, the usual method of burning the string by which the bob is tethered was employed. Thirty-three observations of the hourly motion of the pendulum plane were made during February and March of the present year, and the mean result was 11° 48′, the calculated value being 11° 53′ 37″. The time of the earth's rotation, or length of the sidereal day, thus deduced is 24h. 7m. 30s., an amount only about 11m. in excess of the true time. Foucault's observations gave 23h. 35m. 57s. as the time of rotation. Particulars of the Waterford experiment, and an explanation of the principles involved, are given by Dr. M. F. O'Reilly in *Engineering*, July 5.

THE SUN'S PLACE IN NATURE.[1]

VIII.

TWO objections, however, have been made to these hypothetical two swarms. It has been urged that the secondary swarm which we saw moving in a closed orbit round the primary one would soon spread out into a line along the orbit, so that there would always be some parts of it mixed up with the constituents of the parent swarm. That is a perfectly fair objection, supposing we are dealing with millions and billions of years, but I think that those who have made it do not know the history of astronomy. Let us take, for instance, the history of the November swarm which cuts the earth's orbit, so that in certain Novembers, generally about thirty-three years apart, we get this swarm of meteorites passing through our atmosphere, getting burnt out in that passage, and giving us one of the most magnificent sights which it is possible for mortals to see—a whole hemisphere of sky filled with shooting stars. Some of you may remember such a phenomenon as that in the year 1866, some of us are hoping to see the recurrence of it in 1899, for which we have not long to wait. But the fact that we only get this appearance every thirty-three years shows that, at all events, that swarm of meteorites to which the phenomena are due has not changed during our life-time—nay, it has not changed during the last thousand years, for man has known of that November swarm for more than a thousand years, and we have only known of the variability of Mira for 300 years; so that you see such an objection as that is entirely out of court, because it lacks the historical touch.

Another objection which has been urged is that there are certain irregularities in the light-curves of these bodies; that Mira, for instance, does not always come up to the same amount of brightness at its maximum, and perhaps, for all we know, does not always go down to the same low magnitude when it is at its lowest. That also is perfectly true, and on this account: there is no reason why we should suppose that these phenomena of the waxing and waning light of the body are produced by the movement of one body only; suppose, for instance, that there is some cosmic eye a billion miles away from our solar system, so beautifully and exquisitely wrought, so delicate in its construction, that it can see an increase in the light of the sun every time a big comet goes round it. Now we know from our own experience of comets that it would be absolutely impossible for that delicately constructed eye to see anything like a constant variability in the light of the sun under these conditions, because sometimes the brightest comets which come to us are absolutely unpredicted, they come at irregular times. It must also be pointed out in connection with this objection that there are other obvious causes for considerable variations in the light, both at the maximum and at the minimum. You remember that I showed you those beautiful spiral nebulæ of which Dr. Roberts has given us such magnificent photographs; suppose them to represent the parent swarms, and that another minor swarm tries to pass them; it is impossible to imagine that the minor swarm would exactly pass through all the intricacies of those magnificent spirals, and go and come through it precisely on the same path. It would be certain that in consequence of perturbations, the secondary swarm would sometimes go through a denser portion, at other times through a less dense portion, and then you see that would be quite sufficient to give us a considerable difference of luminosity.

I have another interesting series of diagrams, which will show you that almost any amount of variability and *irregular* variability in the light curves of these bodies may be explained on very simple grounds, supposing we acknowledge that we are dealing with the movements of more than two bodies. For instance, suppose we have one cause at work which gives us a maximum and minimum, and another cause which gives us two very much smaller maxima and minima occurring at a different period represented in Fig. 34 in the upper part of the diagram.

If we add these two together, we get the irregular light curve shown below the two simple curves in the diagram. But the amount of irregularity may possibly only reveal the amount of our ignorance, and when the time comes when we can isolate these two causes, and thus see how the addition of them should be made, we shall find that every part of this curve is really the result of a most beautiful law. I am very glad to say that quite recently Mr. Maxwell Read, of the Harvard Observatory, has put forward this very same suggestion, so that we may hope that it will soon be worked out on pretty broad lines.

But suppose for a moment that this view of two bodies is not accepted. What have we got in place of it? Well, we have to explain all the phenomena of variability by one body. That has been attempted more or less happily. Suppose, for instance, we have the case of a body waxing and waning quite regularly; you have only to say that body is like a soup-plate, and rotates on an axis, so that sometimes you see the face, sometimes only the edge. But that is not very satisfactory, because we do not know any stars which are like soup-plates. Another way is to say that the stars which are variable have great dark patches on one side of them, great bright patches on the other. Well, of course you can get a variation of light by such a scheme as that; but we have not observed that, we are simply inventing, merely suggesting ideas to nature that I fancy nature will tell us by and by are quite erroneous. For instance, I have shown you the facts with regard to β Lyræ. What is the explanation put forward for the variability of that star? Simply this, that it is a surface of revolution, the ratio

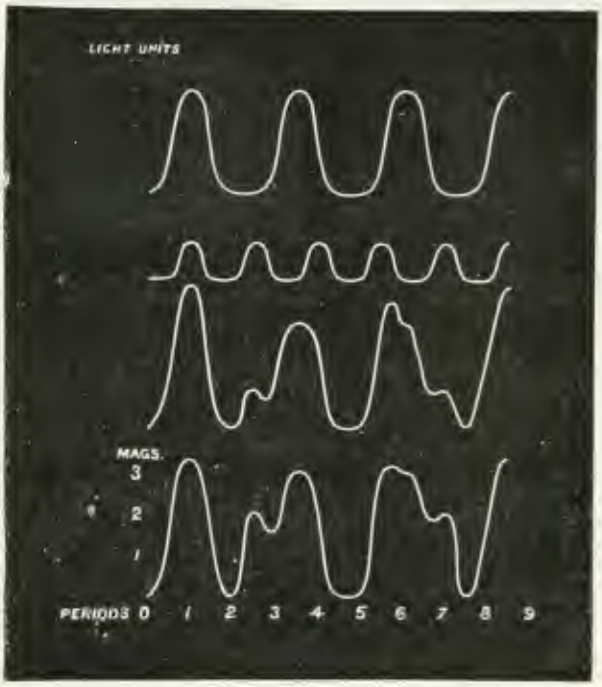


FIG. 34. Indicating how apparently irregular light-curves may be due to the summation of two regular light variations.

of the axes being 5 to 3, *i.e.* elliptic beyond any experience of ours with regard to any other bodies; there is a dark portion at one end of the axis symmetrically situated. This thing then has to turn and twist with its axes and the black spot, and so on, and at the end of the chapter you are to have such a light curve as that of β Lyræ. That you see is blown into thin air by the spectral facts. I think you will acknowledge that these things are irrational, because they have no true basis of fact, and we must remember that in all this work we must deal strictly with the facts in accordance with the rules of philosophising; *i.e.* we must never have a complicated explanation until we are perfectly certain that a simpler explanation will not do, and the simplest explanation of all is that which occurs most frequently in the region of facts. That puts the soup-plate theory with regard to variable stars entirely out of court. Further, remember that supposing those gentlemen who still hold to the one-body theory, one star, one variability, object to the possible explanation of variability by the meteoritic hypothesis, they will find it very much more difficult to explain the departure from regularity by any geometric system, because a geometric system must certainly be

[1] Revised from shorthand notes of a course of Lectures to Working Men at the Museum of Practical Geology during November and December, 1894. (Continued from page 207).

more rigid than any other, and therefore any irregularity under it would be almost impossible.

Closely associated with this reference to double swarms in the case of variable stars are the phenomena of so-called "new stars." Indeed, the whole conception of the meteoritic hypothesis arose from a consideration of those bodies which sometimes quite suddenly make their appearance in the heavens. We have had during the last thirty years five of these new stars, and it was during the appearance of one in the constellation Cygnus in 1876 that I was led to the views which I still hold with regard to their origin.

One of the most remarkable features of these new stars is the rapidity with which they lose their brilliancy, and it was this

1 2

Fig. [illegible] The region in the heavens where Nova Aurigæ was observed (1) after its appearance; (2) when brightly visible (nearly in the centre).

which led me in 1877 to write, in connection with Nova Cygni (Nature, vol. xvi. p. 413, 1877): "We seem driven, then, from the idea that these phenomena are produced by the incandescence of large masses of matter, because if they were so produced, the running down of brilliancy would be exceedingly slow.

"Let us consider the case, then, on the supposition of small masses of matter. Where are we to find them? The answer is easy: in those small meteoric masses which, an ever-increasing mass of evidence tends to show, occupy all the realms of space. . . . The Nova now exists as a nebula, so far as its spectrum goes, and the fact not only goes far to support the view I have suggested, as against that of Zollner, but it affords collateral evidence of the truth of Thomson and Tait's hypothesis of the true nature of nebulæ."

we get the greater light formed at the moment when two swarms, one revolving round the other, are nearest together.

Fortunately for science, one of these new stars appeared in 1892; it is known as Nova Aurigæ, and two photographs will give us an idea of the sort of thing which an astronomer sees in the heavens when the discovery of a new star is announced. The photographs show a portion of the constellation of Auriga, and a star which is very clearly seen in the photograph taken very soon after this star had burst upon us, is absent from one taken a few months later.

Since the spectroscope was first applied to the stars, five new stars have been observed and spectroscopically examined. One appeared in Corona Borealis in 1866, one in Cygnus in 1876, and one in Andromeda in 1885; then came the one in Auriga in 1892, to which reference has already been made, and last of all was one in the southern hemisphere, discovered in 1893. The first three of these were observed by eye only, but in the two recent ones we have the immense benefit of photographic records.

It was therefore a very interesting point when a new star came along, to see whether there was any additional light thrown by it upon the problem of two bodies; and further, upon one of the points in which, if the meteoritic hypothesis failed, it was worth absolutely nothing at all. If there was any truth in the idea of the light of these bodies being produced by the clash of meteor-swarms, when the clash was over the swarms should go back into their native obscurity, or condition of low temperature, and should, if they were seen at all, put on the spectrum of sparse swarms in other parts of the sky: that is, they should put on the spectrum of a nebula.

That, you see, was a very crucial point; it was a point which could be settled by the spectroscope, provided always we had one of these marvellous bodies at such a distance from us that we could still observe it spectroscopically, and see what the different changes really amounted to.

Already in the case of Nova Cygni, the spectrum had been observed to change from a rather complicated one of bright lines and flutings to a very simple one, similar to that of a planetary nebula. The observations did not, however, furnish any direct evidence that more than a single body was concerned in the outburst.

The appearance of Nova Aurigæ, however, furnished a splendid opportunity of testing the many theories which have been at various times advanced to account for the phenomena. This Nova was discovered at Edinburgh by Dr. Anderson, who was modest enough to announce his discovery by sending an anonymous post-card to Dr. Copeland, the Astronomer Royal for Scotland, on February 1, 1892. It was then a star of the fifth magnitude, and on confirming the true nature of the newly-discovered star by means of the spectroscope, Dr. Copeland made the news public. Information was received at most observatories on February 3, and on the same evening two photographs of the spectrum were taken at South Kensington. During the next two or three weeks the star fluctuated considerably in brightness, though being generally on the down grade; and by April 26 had fallen to the

Returning to the subject of new stars in 1887, in a general discussion of the meteoritic hypothesis, I saw no reason to change my views, and an inquiry into the spectroscopic phenomena led me to state that: "New stars, whether seen in connection with nebulæ or not, are produced by the clash of meteor swarms, the bright lines seen having low temperature lines of elements, the spectra of which are most brilliant at a low stage of heat."

A very detailed investigation of all the new stars which had been observed up to 1890 formed the subject of a communication to the Royal Society, and it was shown that the hypothesis would explain the fluctuations of light, the changes of colour, and the spectroscopic appearances.

To make a very long story short, it was suggested that the phenomena of new stars were produced by exactly the same cause as that which was at work in the variable stars in which

10th magnitude, so that it could only be picked up at all in the very largest telescopes. Thanks to the photographic records of the stars, it was possible to learn something of the earlier history of the new star. It had really been photographed by Prof. Pickering two months before its existence was known.

Fig. 30 shows us a photograph of the spectrum of this wonderful star itself, and it will be seen that in the case of all the chief lines we get a bright line and a dark line side by side. There are the hydrogen lines; that is, in the spectrum of that body we were dealing with the giving out of hydrogen, and the absorption of hydrogen. Now, the same set of particles cannot be producing bright and dark lines at the same time. We were then obviously dealing with two sets, and the first photograph, therefore, which was taken of the spectrum of this strange body, put beyond all question the fact that we were really dealing with two

bodies, and not with one. That was very important; but you will see from the photograph, that it is very unlike the spectrum of nebulæ, so that it required a certain amount of faith when the spectrum was observed to be such as you see it here, to suppose that after a certain time, when the action which produced the greater luminosity was reduced and the light toned down, we should eventually get the spectrum of a nebula.

Well, as a matter of fact, the Nova reappeared in August 1892, and was observed to have increased in brightness from the 16th magnitude in April to about 9th magnitude. What, then, was the spectrum? It had almost completely changed; and among the first to observe the new spectrum was Prof. Campbell, of the Lick Observatory. This observer then stated that "the spectrum resembles that of the planetary nebulæ." In the following month the spectrum was also observed by Drs. Copeland and Lohse, and their observations seemed to them to "prove beyond doubt that Nova Aurigæ is now mainly shining as a luminous gas nebula." The most striking evidence on this point, however, is that afforded by the photographic investigations of Von Gothard. He not only shows us the photographic

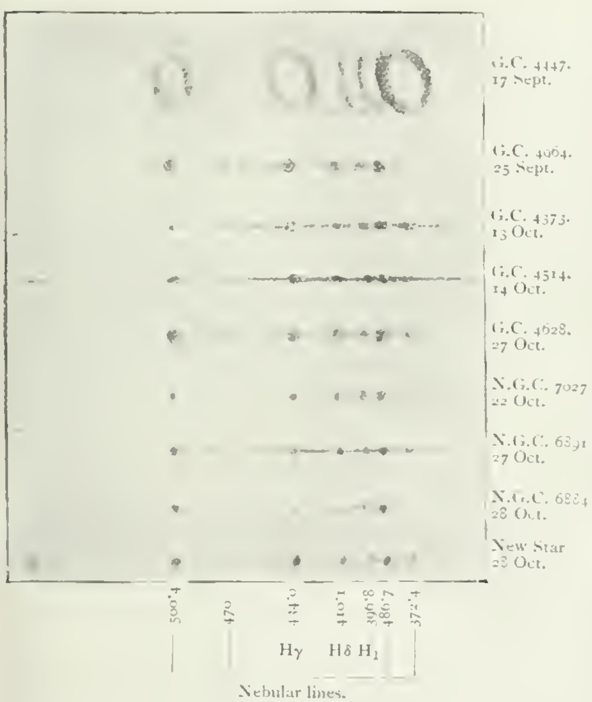

FIG. 37.—The spectrum of the new star in Auriga, as compared with the spectra of planetary nebulæ (Gothard).

spectrum of the new star at this stage of its history, but gives us also the spectra of several nebulæ to compare with it; and it is evident that we were certainly dealing, in the case of the Nova, with the same spectrum as in the nebulæ. Dr. Gothard, at least, was satisfied on this point, and stated that "the physical and chemical state of the new star resembles at present (September and October 1892) that of the planetary nebulæ."

So you see we get, first of all, the hard fact that the spectrum indicated the existence of two bodies; and then the very much harder fact for some, that, after the war was over, we got back to the condition of the nebulæ. I need not tell you that there is not universal agreement on this point, and chief among those who do not yet acknowledge it are Dr. and Mrs. Huggins. Writing of their observations of February 1893, they say: "We wish to speak at present with great reserve, as our knowledge of the Nova is very incomplete; but we do not regard the circumstance that the two groups of lines above described fall near the positions of the two principal nebular lines as sufficient to show any connection between the present physical state of the Nova and that of a nebula of the class which gives these lines."

But I may say, at all events, that I have the great authority of the names of Campbell, Copeland, and Gothard, who state that they have certainly observed the spectrum to be that of the nebulæ, and in reply to Dr. Huggins, Prof. Campbell says: "If the spectrum is not conceded to be nebular, I must ask what else we should expect to find in that spectrum, if it were nebular?" The answer to that is, that you would not expect to find anything else because it is all there already. In fact, out of nineteen lines observed or photographed by Prof. Campbell in the spectrum of the Nova, eighteen correspond perfectly with nebular lines. "Therefore the spectrum is nebular, and the fact that the lines have remained broad, or may have remained multiple, does not militate against the theory."

Further, there is even telescopic and photographic evidence of the fact that Nova Aurigæ became a nebula. Dr. Max Wolf's photographs of the Nova and its surroundings in 1893, resulted in the discovery of a number of new diffuse nebulæ in its vicinity, "and there even appeared to be traces of nebulous appendages proceeding from the star itself."

Another new star appeared in the southern constellation Norma in 1893. This was discovered on October 26, on a photograph taken at Arequipa, Peru, on July 10, 1893. Fortunately the photograph was one showing the spectra of stars instead of the simple images of the stars themselves, and the spectrum was seen to be identical with that of Nova Aurigæ. Even more important were the observations of Campbell in February and March 1894, when the star was about 10th magnitude. As the result of his work, he stated that "there can be no doubt that the spectrum of Nova Normæ is nebular."

THE FLUORESCENCE OF ARGON, AND ITS COMBINATION WITH THE ELEMENTS OF BENZENE.[1]

M. BERTHELOT read the following paper, containing observations by M. Deslandres and himself, before a recent meeting of the Paris Academy of Sciences:—

I have thought it useful to study more closely the conditions of the combination with benzene under the influence of the silent discharge and those of the special fluorescence which accompanies it.

M. Deslandres, whose great competence in spectroscopic questions the Academy is well aware of, has been kind enough to help me in these new determinations, made with higher dispersion, and rigorously determined by photography. It is my duty to thank him here for this long and laborious work.

We must remember that the combination of argon with the elements of benzene, under the influence of the silent discharge, is a slow process; according to the present research, it is accomplished with the help of mercury, which intervenes under the form of a volatile compound. The use of very frequent discharges appears not to modify the general characters of the reaction.
